Smallpox.—Reports received by the Marine Hospital Service for the week ending February 8 show that there are now 12,122 cases of smallpox in the United States, as compared with 4,359 at the same period in 1901. The number of deaths from smallpox for the week was 290, as compared with fifty-five for the same week of last year. In this city every effort is being made by the authorities to protect the citizens by vaccination, and the following free vaccination stations, in addition to those at the Department Headquarters, at Sixth avenue and Fifty-fifth street, and the old headquarters in Brooklyn, have been opened: 68 Elm street, Manhattan; 1237 Franklin avenue, Borough of The Bronx; 38 and 40 Clinton street, Brooklyn; corner of York avenue and Richmond Terrace, New Brighton, Borough of Richmond, and 372 and 374 Fulton street, Jamaica, Borough of Queens. It has been decided to remove all smallpox patients in Brooklyn in future to the Contagious Disease Hospital in Kingston avenue instead of the hospital on North Brother Island, so as not to expose them to the long trip up the river. The force at the Kingston avenue hospital will probably be increased. The Board of Trustees of Bellevue and allied hospitals have issued an order to the effect that all patients received at Bellevue and the allied hospitals should be vaccinated on their reception to the institutions, except where the condition of the patients is such as to render the operation inexpedient.

Parting Xiphopagous Twins.—The cable announces that an operation was performed by Dr. Doyen, on Sunday last, in Paris, dividing the Hindu twins, Rodica and Doodica, two young girls who were united in a manner similar to the Siamese twins. The children were suffering from tuberculosis, and it was thought their chance would be better if each could fight her own malady. It was found that the connection between the two was most intimate, and several large vessels passing from one body to the other had to be ligated. The different steps of the operation were cinematographed.

The Responsibility for Unhealthy Schoolrooms.—A girl recently sued, through her guardian, the Benton Harbor, Mich., School Board for $10,000 damages because of an illness alleged to have resulted from sitting in an unhealthy schoolroom. The Court decided, however, that schools are not liable in private action for injuries sustained through the negligence of school officials.

Dr. James E. Mead Commended.—Surgeon General Sternberg has recommended that Contract Surgeon James E. Mead have a commission as Captain and Assistant Surgeon of Volunteers on account of gallant conduct and professional zeal in the Philippines. This action is taken on the recommendation of First Lieutenant Louis Van Schaick, Fourth Infantry, indorsed by Gen. Chaffee and Lieut.-Col.

B. F. Pope, Chief Surgeon of the Division of the Philippines.

Tetanus Following Vaccination.—Dr. Joseph McFarland, Professor of Pathology and Bacteriology in the Medico-Chirurgical College, Philadelphia, writes that he is engaged in a critical analysis of cases of tetanus following vaccination, in the hope of determining their etiology, and desires to secure all the data possible, and will therefore be greatly obliged to any who may have had or know of cases of tetanus following vaccination if they will communicate with him concerning them.

The End of an Unnecessary Isolation.—Dr. Louis Knapp, who, five months ago, took leave of the world and shut himself up with a Chinese leper in St. Louis, is reported to have tired of his isolation and his studies of the disease, and to have resigned his charge and returned to his family. There is no apparent reason other than the timidity of the officials, why he cannot continue his investigations into the Chinaman's disease without depriving himself of the society of his family and friends.

Obituary Notes.—Dr. M. L. Herr died at Lancaster, Pa., on February 8, of paralysis, at the age of sixty-three years. He was appointed a medical cadet while a student at Jefferson Medical College during the Civil War, and assigned to the army as an assistant surgeon. He remained in the army until 1867, when he completed his medical studies in Nashville University. He organized the Lancaster Pathological Society, was its first president, and was president of the Lancaster County Medical Society at the time of his death. He was a frequent delegate to the meetings of the State Medical Society, and he was in 1890 delegate of the American Medical Association to the International Medical Congress held at Berlin, and in 1894 to the Congress held at Rome. It was largely through his influence that the Lancaster Board of Health was organized, and he was president of that body for some time. He was chief surgeon to local hospitals, and lecturer on anatomy and physiology at Franklin and Marshall College.

Dr. Samuel S. Engle died at Ephrata, Pa., on February 3, at the age of sixty-nine years. He was ordained a minister in the Lutheran Church in 1869, but he subsequently entered upon the study of medicine, receiving his degree in 1875.

Dr. Adam Trau died at Philadelphia, on February 7, of paralysis, at the age of sixty-two years. He was a native of Germany and a graduate of the University of Heidelberg, subsequently receiving his medical degree from the University of Pennsylvania. He served in the Army during the Civil War, and was also a surgeon in the United States Navy. He was chief consulting physician to the German Hospital, with which institution he had been connected for twenty-five years, and of whose medical board he was for many years president, and, at the time of his death, president emeritus.

Dr. William Murray Weidman of Reading, Pa., died suddenly of heart disease on February 8, at the age of sixty-five years. He was a graduate of the medical department of the University of Pennsylvania in the class of 1860. He served in the army medical department through the Civil War. He was an ex-President of the Pennsylvania State Medical Society, of the Medical Society of the County of Berks, and of the Reading Medical Association, and was consulting physician to the State Asylum for the Chronic Insane at South Mountain and St. Luke's Hospital, South Bethlehem.

Dr. Edwin Wollaston Pyle of Jersey City died on February 7 of pneumonia. He was born at Unionville, Pa., in 1849, and was graduated from the medical department of the University of Pennsylvania in 1873. He began practice in Jersey City that same year, devoting special attention to diseases of the ear, nose, and throat. A widow and four children, the eldest also a physician, survive him.

Dr. Bowman H. Shivers died at Haddonfield, N. J., on February 1, at the age of sixty-five years, as a result of pneumonia and nephritis. He was graduated from the medical department of the University of Pennsylvania in 1858.

Obituary.

PAUL FORTUNATUS MUNDÉ, M.D., LL.D.

NEW YORK.

Dr. Paul F. Mundé died at his home in this city on February 7 of disease of the heart. He had been seriously ill for about two months. Dr. Mundé was born in Dresden, Saxony, on September 7, 1846, and when three years old was brought to this country by his parents, his father being a political refugee. He was educated at the Boston Latin School, and then began the study of medicine at Harvard. During the Civil War he served for a time as a medical cadet in the army, and at the close of the war resumed his studies, being graduated from the Harvard Medical School in 1866.

The same year of his graduation Dr. Mundé went to Europe, and entered the Bavarian army as volunteer assistant surgeon in the Austro-Prussian, or "Seven-Weeks' War," and received the cross of civil merit at its close. He then went to Wurzburg and took up the special study of obstetrics, being for three years clinical assistant to Professor Scanzoni in the Lying-in-Hospital, and for two years tutor to the School of Midwives. He completed his obstetrical studies in Vienna, where he obtained the degree of Master of Obstetrics in 1871. Prior to that time, however, the Franco-German War broke out, and he again entered the Bavarian army, being attached as battalion surgeon to the Second Corps. At the siege of Paris a shell from the French artillery set a German field hospital afire. Dr. Mundé, who was a man of great physical strength, rushed to the hospital and carried out a number of the wounded. For this the Emperor decorated him with the Iron Cross. At the close of the war he took his discharge, receiving the service medal, and also the medal for non-combatants. After completing his studies in Vienna, Dr. Mundé visited the schools and hospitals of Heidelberg, Berlin, Paris, London, and Edinburgh, and returned in 1872 to this country, beginning his practice in this city. For several years he was Professor of gynæcology at Dartmouth College, which gave him the degree of LL.D. Later he held the same chair at the New York Polyclinic.

Dr. Mundé was editor of the *American Journal of Obstetrics* from 1874 to 1892, was president of the New York Obstetrical Society from 1886 to 1888, and president of the American Gynæcological Society in 1897 and 1898. He was an honorary fellow of the Edinburgh Obstetrical Society, and honorary president of the International Congress of Obstetricians and Gynæcologists in 1897 and 1899.

He was for a time assistant surgeon to the Woman's Hospital, and since 1881 was gynæcologist to Mt. Sinai Hospital. He was also consulting gynæcologist to the Mothers' and Babies' Hospital and the Skin and Cancer Hospital, and consulting obstetrician to the City Maternity Hospital. In addition to numerous articles contributed to the *American Journal of Obstetrics*, he was the author of the article on "Obstetrics" in Johnson's Cyclopedia, and published two works on "Obstetric Palpation" and "Minor Surgical Gynæcology."

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PARLIAMENTARY—SMALLPOX NOTES—OBSTRUCTIVE JAUNDICE—UNIVERSITY OF LONDON AND UNIVERSITY COLLEGE—HOSPITAL FUNDS: GUY'S, ST THOMAS—MR PLIMMER—DR CAYLEY—MEMORIAL TO DR MYERS—P M O FOR INDIA.

LONDON, January 24, 1902

The Midwives bill is with us again, having obtained a good place in the ballot. It is down for February 26, and unless the government should be obliged to take that day the second reading will be proposed and discussed. The opponents of the bill will do well to marshal their forces without delay.

General Laurie has secured February 12 for his bill to extend the Medical acts. Sir J B Tuke's bill to amend the Scottish Inebriates act is put down for March 12. The ballot has not been particularly favorable to the advocates of measures specially interesting to the profession, and there is much talk of getting in some by other means, but there is no likelihood of that being done.

There was a rather serious debate on the housing question with a futile attempt to shelve it by the promise of a committee.

The Local Government Board has appointed a committee on the nursing of the sick in workhouses. Many of the smaller ones find a difficulty in obtaining efficient nurses. One reason is that they are often overworked and yet underpaid. In some cases the dietary is complained of and in others the sleeping accommodations. Not seldom these are both inadequate. These and other alleged grievances will doubtless be investigated by the committee, which can hardly fail to find room for improvement.

Only seventeen cases of smallpox were notified yesterday, but there were thirty-five the day before, and thus the epidemic goes on with the usual variations in the daily records. Some other towns have been infected by visitors or tramps. Against the latter the government board has warned the local health officials.

The criminal recklessness of some persons would be humorous were it not so dangerous. Thus a man being told by a doctor at Brighton that he had symptoms resembling smallpox, instead of seeking further advice, took the train to another town, where, fortunately, his appearance excited the fears of his landlady, who sent for her medical man. He found her lodger had the disease, and had him conveyed to the isolation hospital.

There is an outbreak at Liverpool which has been traced to some cattlemen from your side. Eighteen cases are in hospital, but it is believed the outbreak is well in hand.

Some city people are insuring against smallpox at Lloyd's. Policies are issued for twelve months for £50 upwards. The present premium is ½ per cent. for those recently vaccinated, ¾ per cent. for others.

Last night there was quite a little breeze in the House of Commons about the government lymph being restricted to public vaccinators. The president of the local government board said 480,000 tubes had been issued for the metropolitan district officials, but he could not supply private practitioners. In reply to questions, Mr. Long has admitted that the government were aware of the increase of smallpox near Purfleet. He thought the Asylums Board were doing everything in their power for the reception and care of patients, and looking at the large number of cases, he did not at present propose to interfere with their discretion. He was not aware that further legislation was necessary on account of the epidemic.

The authorities of the government departments seem to have been awakened by the meeting of Parliament to the existence of the epidemic, and have requested their employees to be revaccinated. Even the war office has been stirred to action.

The Medico-Chirurgical has before it a resolution in favor of the government lymph being supplied to all practitioners, and until that can be done, testing imported lymph and inspecting the processes of production employed in this country. The resolution will be considered at the adjourned discussion on vaccination next week.

Last week I gave you an outline of a discussion at the Clinical Society on Mr. Mayo Robson's paper on "Intestinal Obstruction." This he followed up three days later with a paper at the Medical Society on "Obstructive Jaundice Resulting from an Experience of over 200 Operations." He takes a more hopeful view from a surgical standpoint than formerly. Of course the chief point is the cause. Medical treatment must be employed in cases dependent on gastritis involving the ducts and in chronic duct catarrh. In malignant disease surgery can do little good unless in very exceptional cases admitting complete removal. In gallstones, simple stricture of the common duct, inflammatory adhesions causing pressure on or stenosis of a duct, and in hydatids of the liver pressing on or discharging into the ducts, he advises operation. In doubtful cases an exploratory operation can be resorted to provided the state of the patient does not render the risk too great. In primary cancer of the liver or pancreas, Mr Robson admitted the futility of surgery. Yet he held that in young patients with cancer of the head of the pancreas, the question should be considered, as malignant disease of the pancreas is not common before middle age. With regard to gallstones and the other obstructive causes he had named as suitable for operation there should be no delay. Out of 212 such cases he had had 183 recoveries. The two chief dangers were hemorrhage and shock. Next to them came exhaustion and sepsis. Against hemorrhage he gave large doses of calcium chloride, thirty grains three times a day for two or three days before operating, and dram doses in saline solution per rectum afterward. Against shock strychnine in large saline enema a half an hour before the operation. Still more important was expedition in operating, the most complicated cases could be completed in an hour.

Mr Morgan also spoke of the importance of rapidity in abdominal operations, but Mr J. Hutchinson, Jr., demurred to this, and said slower operations in the lower abdomen had been most successful, instancing resection of intestines by suture and gynecological operations.

Mr. Barker was in favor of celerity, and urged the necessity of keeping patients warm and eliminating delay by careful preparation beforehand. He also alluded to cases which had recovered after exploration, though they appeared malignant.

Mr Eve supported exploratory operation in doubtful cases, and Mr Spencer thought the duration of the disease a point in diagnosis, as rapid course suggested the head of the pancreas as the seat.

Mr. Robson in his reply, said that in his experience of twenty-four cases of cancer of the head of the pancreas, operation was of no benefit, and the mortality was 50 per cent. Rapidity was less important in the lower abdomen, as there was much less shock in those cases.

On Wednesday, at the meeting of the Senate of the University of London, it was announced that the Drapers Company would be responsible for the debt of University College to the tune of £30,000 provided the college be incorporated in the university by September, 1903. An anonymous donor is also prepared on the same condition, to devote £1,000 a year to the college—a sum redeemable by his executors at £30,000. A committee was appointed to confer with a committee of the college. The latter body seems to be imitating the coy maiden, for there is a talk of appealing to the public for funds to enable it to negotiate with the university on a better footing. I doubt if the public will respond, and would advise the maiden to accept the dowry without demur.

The treasurer of St. Thomas' Hospital has issued an appeal for funds on account of increased expenditure in recent years without any increase to its permanent income. Nearly £10,000 is needed to balance the account.

A "renovation and building fund" for Guy's Hospital was started at the Mansion House on the 15th inst. The Lord Mayor appealed to the citizens to make good the deficiency of about £25,000 a year. It is estimated that £180,000 will be required for the new works, of which sum between £60,000 and £70,000 has been promised.

Mr H G Plimmer of St Mary's Hospital has been requested to act on the committee for investigating cancer appointed by the German government. There is some talk here of the Royal Colleges undertaking researches on this disease, but to do so they would need an adequate endowment, and where is the donor?

Dr Cayley, senior physician to the Middlesex Hospital, has retired after a service in various positions of thirty-five years. On the 9th inst. he was entertained at dinner by former house physicians, and presented with a loving cup amidst enthusiastic expressions of esteem.

In memory of Dr Walter Myers, whose death you will remember occurred from yellow fever while investigating that disease for the Liverpool School of Tropical, his father has endowed a traveling studentship in the University of Birmingham.

Colonel Sir T. J. Gallwey is to go to India as P.M.O. in succession to Surgeon-General Taylor, who has become director-general.

Progress of Medical Science.

The Boston Medical and Surgical Journal, February 6, 1902.

A Plan for the Municipal Control of Tuberculosis in Boston.—Agnes C. Vietor suggests that an unpaid municipal tuberculosis committee of men and woman be appointed with sub-committees on air and light in tenements and other buildings; on cooking and savory serving of food on a large enough scale to give the poorest a chance to be well nourished; on employment; on dust and noise; on nursing and disinfection, and so on. A model sanatorium should be erected in each section of the city, as a practical example of the method of living which cures. To these sanatoria selected patients should be sent for short periods, to learn the lesson by actual experience; returning to their homes, they will themselves be teachers to ever new and widening groups. In such organized work alone lies any hope of eradicating the scourge of tuberculosis, since the extermination of the bacillus outside of the body is impossible, its strong entrenchment being in the bodies of people in a condition of lowered vitality; and the great sources of such lowered vitality being (*a*) insufficient food, (*b*) insufficient air and light, (*c*) overwork, (*d*) worry. Therefore the fundamental factor in the existence and increase of tuberculosis is the health of the mass of the people. The only definite decrease in tuberculosis yet recorded is in (*a*) cures effected in patients who adopt some modification of open-air life, with superfeeding and freedom from overwork and worry; (*b*) improvement in New England statistics, the only changed factor of general extent being the use of the bicycle and recreations increasing open-air life; and (*c*) the decreasing statistics of tuberculosis in German villages where tuberculosis sanatoria are established, the villagers consciously and unconsciously imitating the example of the sanatoria patients in their mode of living.

Journal of the American Medical Association, Feb. 8, 1892.

Primary Sarcoma of the Œsophagus and Stomach.—W. T. Howard, Jr., has found eleven cases of this rare affection, and adds an additional case. His patient was a man aged fifty-one years, suffering from vomiting and dysphagia, who died of exhaustion a few weeks after coming under observation. The autopsy findings were as follows: The œsophagus was of normal size and appearance from its beginning to within 12 cm. of its cardiac end. At this point its wall was much thickened, and its mucous surface was the seat of irregular ulcers, covered with grayish necrotic material. The surface was irregular, but there were no polypoid masses projecting into the lumen. On section the wall was rather thicker than usual, firm and dense in consistency, and pale in color. The cardiac orifice of the stomach was narrowed, but admitted the little finger with ease. The stomach was of ordinary size, and appeared normal throughout, except for the thickening of the cardiac orifice above described, and for the presence near the latter of a nodular tumor, 7 cm. in its greatest diameter. On section this mass was seen to be beneath the mucosa. It was dense and firm, and on section was glistening in appearance. Some of the lymph glands near the stomach were enlarged. There were no other metastases.

The Problems of Heredity.—J. G. Kiernan states that the mother is the great factor in heredity. Paternal heredity is a prophecy of what may not be a destiny. A healthy mother may offset the paternal defects of a generation. There can be no doubt that maternal shock exerts an influence on the fœtus. The question, however, as to the fact of this influence, method of action, and results must be determined by an analysis of the period of pregnancy at which the shock is experienced. Unfavorable surroundings act similarly. Hence the significance of the fact that 92 children born in Paris during the siege of 1870-71, 64 had slight mental or physical anomalies; the remaining 28 were all weakly; 21 were weak-minded, and 8 were subjects of moral imbecility. In Berlin the financial crisis of 1875-80 was followed by an increase in the number of idiots born. The nutrition of the mother may thereby be so disturbed as to result in a partial toxæmia, which tends to disturb development of the fœtus *in utero*. Thus a nexus of cause and effect can be traced. Early involvement of the germ is shown in the fact that somatic malformations in the hereditary psychoses often affect the body elsewhere than the nervous axis. The stigmata of heredity—defective development of the urogenital system, deformities in the face, skull, irregular growth of the teeth, misshapen ears and limbs—owe their grave significance to this fact. Like deformities of the brain, these anomalies are also more marked and constant with the lower forms of the hereditarily based systematized perversions of the mind than the higher.

Autotoxæmia as a Factor in the Neuroses.—G. F. Butler points out the relation between autotoxæmia and certain conditions, such as scorbutic disorders, fatigue fever, etc., and then studies some of the neurotic states caused by the same toxic factors. There arises a prolonged neuropathy with suspicional and anxious tendencies. This condition mimics all the chronic neuroses, and is often mistaken for them. So, also, we may have a condition simulating acute confusional insanity or melancholia, and occasionally emotional exaltation, creating a suspicion of paretic dementia. In many cases charged to mental shock autointoxication is the dominant cause. A similar explanation will account for certain cases of transitory frenzy, with wild, brief, unremembered violence. Examples of the foregoing or similar states are seen manifesting themselves through aural, nasal, laryngeal, and pharyngeal states. The predisposing cause, however, in the latter class may remain to set up recurrence of autotoxæmia and its consequences if untreated. The pure type of autotoxæmia underlying many of the so-called reflex states was formerly known as fecal anæmia. The obvious deduction from all the foregoing is constantly to bear in mind the fact of possible autointoxication in cases which baffle us, so far as concerns the determination of the exciting cause. The therapy of this class of cases will naturally depend on the type. A change of surroundings, regulation of diet, use of mineral waters, exercise, massage, and hydrotherapy are all useful. The bowels must be carefully looked after. In old people salines must be used cautiously. Electricity is a valuable adjuvant. The author calls special attention to the pseudo-angina frequently accompanying autointoxication, stating that it has received less attention than it deserves. Sometimes, albeit very rarely, death has occurred from this. This condition is due to the primarily increased inhibition of the heart, succeeded by increased power of the excitomotory ganglia of the heart with resultant irregular action. From this often results the emotional exaltation, depression, and suspicional states found in autointoxication of brain and heart. It is readily comprehensible how these irregularities tend to increase each other. Independently of the condition just described, cardiac irregularities occur in autointoxication from arterial tension, due to the character of the blood. Inevitable renal and hepatic disturbances occur, whence the temporary albuminuria and glycosuria.

New York Medical Journal, February 8, 1902.

What Shall We Do with the Consumptive?—A. Fanoni recommends the following measures for the abatement of tuberculosis: (1) Marriages of consumptives should be avoided; (2) Children of consumptives should be so brought up as to strengthen their systems against the invasion of the tubercle bacillus; (3) The public should be educated to realize the fact that consumption is curable in its initial stages, *i. e.* when mixed infection has not yet taken place; (4) An early diagnosis is the secret of cure. Let us drop the word "cold" as a term for a little cough and a subnormal temperature, and the word "malaria" for cough accompanied by chills, and let us examine the patient carefully in each case. When questioning the patient it must be borne in mind that the consumptive, fearing to hear the word "consumption," often tries to disguise his symptoms, and that it is in such cases that the skilful physician proves his ability; (5) Every case of pulmonary tuberculosis should be reported to the local health authorities so soon as the diagnosis is made; (6) Every consumptive should be isolated until cured, or until the disease terminates fatally.

Closure of the Abdominal Incision, with Remarks upon the Cause and Prevention of Ventral Hernia.—I. S. Stone suggests the following principles as those that should guide us in wound closure, asepsis being, of course, premised: (1) Remove all excess of peritoneal flap. Also remove all loose pieces of muscle or fat, as these bits of tissue may become necrotic; (2) Bring peritoneum, muscle, fascia, etc., together to meet similar tissues of the opposite side, without space between layers for collection of serum or blood, and yet without strangulation. The sutures to be placed in such manner as to make pressure as much upon the fascia, or tissues in the center of the circle made by the suture, as at the peritoneal or skin surfaces. The interrupted sutures will answer these requirements in nearly every respect; the exception being its non-absorbability, and also its inability to bring like surfaces together accurately. This method may be used with entire satisfaction when supplemented by additional buried sutures, preferably of some absorbable material, in the fascia. Finally, Stone believes that layer sutures, as generally used, make unnecessary pressure upon the entire wound surface, and prevent proper blood supply, while they are not more effective in preventing dead spaces than the interrupted suture.

Medical News, February 8, 1902.

Cirrhosis of the Liver as Seen in Children.—W. S. H[illegible] believes that cirrhosis of the liver in infants and adolescents is not so infrequent as is commonly supposed, and that cirrhosis in children may generally be relegated either to syphilitic or alcoholic types, with a very small percentage as sequelæ of the acute infectious diseases. As a rule, the predisposing conditions are considered to be some form of gastrointestinal irritation that produces an early [illegible] condition. Congenital [illegible] in infants is most probably syphilitic and is inherited. It is nearly always possible to determine the diagnosis of this disease in the little patient. In older children the disease may be found with an [illegible] history in the other organs. General tuberculosis is sometimes accompanied by cirrhosis of the liver. Two cases are on record of young children with [illegible] [illegible] who were large beer drinkers. It is impossible to discriminate clinically the symptoms of the two forms of cirrhosis, the atrophic and hypertrophic, in the earlier stages.

Percussion of the Lower Border of the Liver.—Albert Abrams declares that a good rule to follow is never to declare the liver to be enlarged unless it is palpable, but a dislocated liver may be palpated, although it may not be enlarged. Again, rigidity of the abdominal walls may obscure the results of palpation. A simple method of mapping out the lower border of the liver is the following: The patient inclines his body backward as far as possible, the body being supported by means of the hands resting on the hips. Percussion, which must be light, will determine the lower hepatic border with minimum difficulty. If strong percussion is used in mapping out the lower border, the air contained in the neighboring viscera will be set in vibration and the desired result—elicitation of a dull sound—will be defeated. One point in the consideration of this subject must not be forgotten, viz., the necessity of clearing the bowels by free purgation before the examination. In conclusion two facts are emphasized: (1) The patient must be cautioned to take no inspiration before contracting the abdominal walls, for by doing so the liver will be dislocated downward; (2) In practising percussion, the finger must be firmly imbedded in the abdominal wall, otherwise the blow will not be directly transmitted to the liver.

American Medicine, February 8, 1902.

Nature of Typhoid Fever.—Eugene Wasdin states that there must be a colonial development of the organism other than in the intestinal canal, as shown by the constant presence of the bacillus in the blood before its presence in the intestinal contents, its presence in the stools only at the end of the first week, in small numbers, its rapid increase to the maximum by the end of the second week, and the presence of the diazo-reaction at this time most frequently. The non-presence of the organism in the blood current until after the advent of toxic symptoms, together with the constant presence of more or less marked signs of colonial development in the lungs, and the expectoration of members of such colony, show that this disease is essentially one of the respiratory tract primarily, the well-known symptoms of the second and third weeks being mainly secondary. If these observations are correct, treatment should be directed more energetically against the primary colony, although the importance of the treatment of the secondary intestinal colony is great. The application of benzyl-acetyl peroxid to the treatment of this disease has been attended with happy results. It has been used both for the primary and the secondary infection, as well as by means of hypodermoclysis to combat terminal expressions. As the mortality in typhoid fever depends mainly upon lung and intestinal fatalities, successful treatment of these conditions will bear happy fruit. Disinfection must also be carefully attended to.

The Aspect of Disease as Seen in Arctic Alaska.—Ernest W. Kelly declares that Alaska, physically speaking, is either an iceberg or a swamp. Sometimes disease is so obscured by the changed conditions of life that the diagnosis is made difficult or even impossible. Among the diseases peculiar to this country are cerebrospinal meningitis, scurvy, typhoid fever, neuralgia, nervous diseases, and the results following exposure to extreme cold. In cerebrospinal meningitis delirium is almost always a constant factor and often carries off the patient. The petechial rash that develops is usually puerpuric in type. The mortality is high. The scourge of the white man in Alaska is scurvy. These two diseases just mentioned rarely attack the natives. In typhoid fever there is a tendency to an absence of rash, a not very high fever, and the association of scurvy and salivation. This condition is often confusing to the physician. The cerebral form is prevalent and is often mistaken for cerebrospinal meningitis. Rheumatism seems to be neuralgic in type. It is rarely attended with much elevation of temperature, often with none at all, but is frequently associated with a neuritis. The heart is rarely if ever attacked. Only one case of pneumonia came under the observation of the writer. The nervous diseases are of two types—those occurring in form due to physical conditions external to the patient, and those psychic in character. The disorders of other organs are few and are limited mostly to [illegible] [illegible] and the results of the various [illegible] changes. There is great suffering from gastrointestinal complaints. The diseases most common to the natives are chronic bronchitis, pulmonary tuberculosis, [illegible] in the same manner, smallpox, [illegible], measles, grippe, and mumps.

Philadelphia Medical Journal, February 8, 1902.

Use of the Rontgen Rays in the Diagnosis of Lesions of the Brain.—Charles K. Mills and G. E. Pfahler conclude from their investigations in this subject: 1. That gliomata, and probably other tumors, can be photographed in the living subject and their location and extent shown. 2. That various tumors can be photographed in their most common locations. 3. That other abnormalities and deformities in brain tissue itself can be photographed which will probably be of value in the diagnosis of cysts, softening, and hemorrhage. 4. That overexposure of the third series and the underexposure of the fourth show that good results will only follow the most careful technique and keen judgment as to the special conditions in each case. 5. That the shadows obtained in normal parts of the brains studied indicate that great care is necessary in the interpretation of any shadow obtained in the living subject.

A Case of Cerebral Bulbar Palsy, with a Study of the Localization of the Tongue and Lip Centers.—Charles L. Dana draws the following conclusions: In the human brain the lip and tongue centers are closely connected and more or less identical. One group of centers for the tongue is in relation with the articulatory movements of the lips, and another with the movements of mastication, opening and shutting the mouth, and deglutition. The area for the excitation of movements of the tongue is a wide one, being associated probably in its lower parts with the articulatory movements, and in the upper parts with the masticatory movements. The centers lie at the base of the pre- and post-central convolutions. The paralysis of the tongue and, to some extent, of the lips occurs from a one-sided cortical lesion, and may perhaps be explained by the fact that in many individuals the brain becomes accustomed to use only one center in controlling the movements of these parts. When this center is destroyed there is for a time a paralysis of the movements. When the center upon the other side becomes awakened to its capacity, it takes up the movements, and the paralysis disappears. This theory may explain, also, the very frequent occurrence of difficulty in deglutition, and often in articulation, in many cases of hemiplegia due to ordinary cerebral hemorrhages. That a permanent bulbar palsy can be caused by a cortical lesion of one hemisphere is doubtful, and if it occurs, must be considered rather as an anomaly.

A Case of Cerebellar Tumor.—James Hendrie Lloyd and T. Perceval Gerson report this case. The patient was a man twenty-one years old. He was admitted to the hospital in a semistuporous condition. There was no history of traumatism. The patient had contracted gonorrhœa, but there was no history of syphilis. There had been intense headache for some months. The patient was utterly oblivious to sound. His speech showed cerebral incoordination. There were no scars on the head. There were several spells of vomiting, one of which was distinctly projectile in character. Towards the end the respirations assumed the Cheyne-Stokes type, the pulse became very rapid, and the temperature rose from the normal or subnormal range to 103.8°. Autopsy revealed a very large tumor lying upon the vermiform process of the cerebellum just below the tentorium. This tumor was easily shelled out of its bed. It had only the slightest connection with the brain substance. It was encapsulated, and had sprung entirely from the membranes. It had flattened and entirely destroyed the appearance of the quadrigeminal bodies and the vermis of the cerebellum. The aqueduct of Sylvius was pervious. The tumor was very vascular. On section it presented the appearance of a sarcoma. There was no infiltration of sarcomatous tissue in the neighborhood. The ventricles were much distended. There were large Pacchionian bodies along the course of the longitudinal fissure, deeply imbedded in the vault of the cranium.

The Lancet, February 1, 1902.

Notes Concerning a Native Remedy for Blackwater Fever.—The remedy mentioned by D. R. O'Sullivan-Beare is a decoction made from the roots of a Cassia which grows in equatorial East Africa from the sea level up to an altitude of 800 feet. The particular species seems not to have been described before, and has been named, in honor of the author, C. beareana. The plant is figured in the article. To prepare it, the natives chop a portion of the root into pieces, each about one inch in length, and of those pieces they boil about one dozen in a gallon of water for half an hour or so. The result is a red-colored fluid, of which the patient suffering from blackwater fever is given to drink, either hot or cold, as often as he feels thirsty. Apparently it is non-poisonous in its action, and may be consumed in unlimited quantity. In cases where the patient does not suffer from marked thirst, the decoction is administered in doses of about a teacupful every couple of hours. The natives employ the same remedy, and they claim for it specific virtues also in the treatment of that simple form of hæmaturia—*i. e.* unaccompanied by febrile symptoms—which is so prevalent amongst the negroes of East Africa. The only portion of the tree, other than the roots, employed medicinally by the natives is the bark, which they powder and apply, as a dressing, to ulcers, apparently with good results.

Ultra-Violet Light from a Rapid Oscillation High-Tension Arc in the Treatment of Skin Diseases.—Hugh Walsam describes and figures the apparatus he has used. He has applied the remedy to cases of lupus vulgaris and l. erythematosus. The former do better than the latter. The time of exposure has been from ten to fifteen minutes. Special stress is laid on compression. Cases in which this can be efficiently applied (as, for example, lupus on the end of the nose) improve much quicker than cases in which the compression is more difficult. At the present time it is somewhat hard to tell whether a given case of lupus will do better with the *x*-rays or the ultra-violet rays. Many observers appear to regard the treatment by *x*-rays and by light as something quite different. When we consider, however, in how many ways ultra-violet and the *x*-rays are alike, the distinction between the two almost vanishes. Both act chemically, both produce fluorescence in bodies, both discharge the gold-leaf electroscope. The action on the skin is, however, somewhat different, although they are both capable of producing dermatitis and pigmentation. In the case of the light treatment, dermatitis supervenes after some hours, whereas with *x*-rays it may require even weeks to produce it. Again, the dermatitis produced by the ultra-violet rays soon resolves, but it is well known that the *x*-ray form may take weeks, or even months, to heal. It is true that *x*-rays have more penetration, but in passing through a body, they generate secondary rays, which have a great analogy to ultra-violet rays. It is probable that secondary rays are Röntgen rays very slightly penetrative, and possibly intermediate between the rays from a soft tube and extreme ultra-violet rays. There is, according to current belief, a great difference in their action on bacteria, the *x*-rays being said to stimulate their growth, while the violet and ultra-violet rays are known to kill. In fact, we may say that the only absolutely sure ground on which we may build is that the ultra-violet rays will kill bacteria outside the body. Other observers are treating cases of lupus with the static breeze and the Tesla condensing electrode. The Tesla electrodes have been used with success in the department, and it appears to me in all these various methods of treatment that the only one point they possess in common is the ultra-violet ray. It has been found that all materials used as compressors or heat arresters obstruct many of the bactericidal rays. Ice, however, has so many advantages, both from a theoretical and practical point of view, that it has been adopted in nearly all cases. These advantages are so important that it may be well to enumerate them: (1) It is hard enough to cause efficient pressure; (2) It adds to this effect by increasing the anæmia by cold; (3) By its transparency it allows the individual lupus nodules to be clearly seen; and (4) It is transparent to the violet and ultra-violet rays of the spectrum and opaque to the red and infra-red.

A Case of Recurrent Sarcoma with Apparently Spontaneous Cure and Gradual Shrinking of the Tumor.—The case is reported by A. L. Watson, whose patient was a strong, healthy woman of thirty-six years, who came under observation simply because a swelling on the back was annoying her, and she wished to have it removed. This tumor was large and pendulous, being attached to the left side of the back by a base nine inches wide and rather less than four inches in vertical measurement; the apex hung down for almost four inches below the lower margin of its attachment to the back, while the upper margin was just below the inferior scapular angle. It was soft, but not fluctuant, slightly nodulated, and had the appearance of a lipoma undergoing degeneration; the skin covering the dependent portion was of a dark reddish color. The tumor was regarded as simple, partly because of its character, and partly because its history went back to the patient's childhood, though it had grown considerably in recent years. It was removed without difficulty. After the operation, hemorrhage was so free that the dressings had to be frequently changed in the first few hours; thereafter they were left for four days untouched. On the fourth day it was observed that the dressings had become tight, and on exposing the back the tumor was found to be almost as large as before operation. In the expectation that this might be due to accumulation of blood-clot beneath the flaps, a portion of the wound was opened up, but no blood could be expressed, even when a director was introduced and worked about inside the wound. It was therefore concluded that the swelling was due to a rapid re-formation of the tumor. The original specimen had been accidentally lost, but at the time of re-formation a piece was removed and pronounced by two microscopists, working independently, to be a mixed round- and spindle-cell sarcoma. A week later the margins of the operative wound began to ulcerate, but when a second operation was about to take place, it was seen that the tumor had attained such a size and was so diffuse in its margins that further radical interference was considered out of the question; the ulcerated edges were therefore cut away, and the wound was again stitched up. During the remaining days of her residence in the infirmary the patient looked and felt very ill and weak. A bad prognosis was given and she was dismissed. To the surprise of all, however, she greatly improved, and the growth diminished in size. One year later, the patient was seen, and the following facts noted: The general health was excellent. The tumor was much less prominent, and hung like a loose sac, as if almost all its contents had been evacuated. There was slight lividity at the margins, but no pain, except an occasional stinging like neuralgia in damp weather. The tumor covered about the same area as at the time of dismissal, but consisted of little more than loose skin. The scar of the operation wound was perfectly sound and firm. No pain was caused by free manipulation, and the clothes were worn without discomfort.

British Medical Journal, February 1, 1902.

Case of Abscess in the Neck, with Signs of Vagus Irritation.—J. Basil Page reports this case. His patient was a boy aged thirteen years. He went in swimming one day for several hours, and the next day had a sore throat, and was sick and feverish. The tonsils were enlarged, but there was no ulceration and no membrane. A swelling developed on the left side of the neck, which rapidly increased, and fluctuation was present. Incision was not permitted. Six days after the first symptoms of illness, something burst in his throat, and he brought up a large quantity of blood and matter through his nose and mouth. The next day he began to vomit, and later had a little diarrhœa, and became extremely collapsed. Ordinary remedies were of no avail. He was very restless, his face was livid, but his breathing was quite easy. The heart was beating at the rate of thirty a minute; its action was regular; there was no murmur. Two days later he died. The writer believes that this may have been a case of irritation of the vagus.

Oophorectomy in the Treatment of Cancer of the Breast.—H. Atwood Beaver raises the query whether in this treatment of cancer of the breast the administration of thyroid extract has not a large share in causing the good results. He reports a case of a woman aged fifty-one years, who was suffering from uterine cancer. The case was so far advanced that the only indication was to relieve pain. A month longer of life seemed more than could be expected. Thyroid extract was begun. The dose at first being five grains daily, but this was quickly increased to twenty grains. The results were wonderful. In about two months the patient was up and free from pain. The various growths were much reduced in size, and the patient was rapidly gaining weight. Some months later she was quite well, and was following an active life. There was nothing abnormal to be felt in the pelvis. Although not arguing from a single case, still the writer thinks that thyroid extract should always be used in this class of cases before more heroic measures are adopted.

Recurrent Carcinoma Treated by the Röntgen Rays.—G. B. Ferguson reports a case of recurrent scirrhous growth, of the size of a hen's egg, on the manubrium of the sternum. The growth was immovable, apparently growing from the bone. There was below it a hardened ulcerated surface two inches square. The left arm was much swollen, and there were extensive deposits in the axilla. The patient had been operated on three years [illegible] the axillary [illegible]. The use of the Röntgen rays was advised. This treatment was kept up for twenty days, twenty minutes at a time. The patient was then obliged to go away for a time. After being gone a month she returned in excellent health and spirits. The mural growth had disappeared, the ulceration had healed, and what pain there was was confined to the arm, the swelling of which had greatly diminished. A twelve-inch spark coil was used, and the distance of the tube from the body was from eight to ten inches. The patient was rather "x-ray burnt" in the face and lost her eyebrows, but these are comparatively trifling matters. In the same institution a case of intractable rodent ulcer was treated by the same method and healed.

The Indiscriminate Use of Atropine in Eye Diseases.—H. Carter Matter warns all medical men to use atropine with the greatest care, and in all patients over thirty years old—the predisposition to glaucoma increasing with age—to use it only in case of necessity, and then only if the patient can be kept under constant observation. He gives the differential points between acute glaucoma and iritis. In the former the pupil is larger than usual and does not react to light. In iritis it is smaller than usual and also fixed. Ophthalmoscopic examination of acute glaucoma shows the media to be hazy, and there will be a grayish green reflex. In iritis there are small exudations in the media, and the pupil's irregularity is due to these binding the iris to the lens. In acute glaucoma the tension will be found increased. In iritis it is normal. In acute glaucoma the loss of vision is out of all proportion to the turbidity of the media, and is greatest on the nasal side. In iritis it is often not diminished except by photophobia. In glaucoma the cornea is generally almost insensitive to touch, while in iritis it is hypersensitive. The presence of vomiting with an inflamed eye is almost diagnostic of glaucoma, though it may occur in iritis. Confirmatory symptoms should always be sought in such cases.

Berliner klinische Wochenschrift, January 20, 1902.

Psoriasis and Glycosuria.—Walther Pick considers the relation of glycosuria to psoriasis. In order to determine whether or no psoriasis is associated with or dependent upon a reduction of the power of the body to assimilate sugar, he selected fifty psoriasis patients and fifty with other skin diseases and observed their relation to alimentary glycosuria. Of the psoriasis patients only two reacted positively to the test, while of those with other cutaneous affections three under these conditions showed glucose in the urine. He believes, therefore, that a reduction in the power of sugar assimilation is not characteristic of psoriasis, and that when glycosuria occurs in this disease it is merely an accidental complication.

Transmission of Syphilis from Parent to Offspring.—W. Friedlander reports the study of the infection of an entire family with syphilis, and brings out several interesting points in this connection. The father became inoculated with the disease while his wife was in the fifth month of pregnancy. He immediately began mercurial treatment. The child was born free from syphilis, and the wife did not contract the disease at this time. Shortly following this the father discontinued treatment, the symptoms of the disease having disappeared. In about a year syphilitic manifestations returned and he again began the use of mercury. Following this the wife again became pregnant, and in due time was delivered of a healthy child. She likewise showed no signs of syphilis. The father now again discontinued treatment, which was never resumed. One year thereafter the wife developed syphilis, and the two children subsequently came down with the disease. Friedländer ascribes the development of the disease in the children to direct contact with an infected father and mother. These cases illustrate how a syphilitic father, under the influence of mercury, can procreate healthy children and not infect his wife, so long as he continues the use of the drug.

Münchener medicinische Wochenschrift, January 21, 1902.

Treatment of Severe Anæmia of Gastrointestinal Origin.—F. Perutz draws attention to this form of anæmia and reports a case, the favorable termination of which illustrates the advantages to be derived from systematic irrigation of the stomach and intestines, together with appropriate alimentation. The diagnosis of the conditions rests upon the examination of the blood and stomach contents. The acidity of the latter is much below normal, and want of proper functional activity of this organ is plainly evident. Every morning the stomach should be washed out with a normal saline solution, and at night an enema of one quart of chamomile infusion should be administered. In this manner two objects are obtained: (1) The removal of obnoxious products of decomposition, and (2) Stimulation of the diseased stomach and intestinal mucous membrane. In severe cases the diet should at first consist of milk (plain or peptonized) and oatmeal gruel, with an egg beaten up in it. Later white meat and bread may be added. As the case progresses favorably, fats should be gradually added, and dark meat or the various meat extracts given. In order to stimulate the appetite, delicacies may from time to time be sparingly partaken of. By following this plan of treatment it is possible ultimately to permanently cure these cases. At the beginning, however, relapses are very liable to occur, and treatment has to be resumed after having been discontinued. Perseverance is, however, regularly followed by an absolute recovery.

"Emulsion-Albuminuria" in Eclampsia and Uræmia.—Heinrich Cramer reports three cases in which this peculiar and hitherto undescribed urine condition was present. The first two were eclampsia, in which the urine was drawn by catheter during coma shortly before death. Previous to this time the urine in both cases had been heavily charged with albumin, so that it became solid upon boiling. The urine taken during coma showed a milky white color, and when boiled did not become solid, but simply deposited an abundant sediment. Microscopical examination showed that the milky color was imparted by the presence of numerous small globules. Cursory chemical examination showed that these were probably albuminous in nature. The third case was one of uræmia, in which the urine was also taken shortly before death. It was entirely similar in character to that observed in the cases of eclampsia mentioned. An extended chemical examination definitely proved that the globules making up the emulsion were of an albuminous composition. Cramer thinks that this "emulsion-albuminuria" is not of infrequent occurrence, although no other cases have been reported. In all of his cases this condition was only present during coma. It is unusual to examine urine in this stage of the disease. As all of his cases proceeded to a fatal termination, the author is inclined to think that "emulsion-albuminuria" necessarily means a fatal prognosis. Whether this is so or not can only be determined by continued observation. This is much to be desired.

Relation between Diabetes Insipidus and Diabetes Mellitus.—Ph. Kuhn thinks that diabetes insipidus and mellitus are closely related conditions, and are not to be considered as entirely independent diseases, as is the custom in many quarters. Numerous cases of diabetes mellitus have been recorded in which the sugar permanently disappeared from the urine while the polyuria remained, thus transforming them into diabetes insipidus. On the other hand, the transformation of diabetes insipidus into mellitus is only very rarely observed. Only three cases of this character have hitherto been recorded. Kuhn now adds another to this list. The patient, a woman fifty-eight years of age, presented a carcinoma of the breast, for which a successful excision was performed. Following the operation, the urine increased markedly in quantity, and became of low specific gravity (1.002 to 1.003). No sugar was present. These characteristics of the urine continued, and the diagnosis of diabetes insipidus was made. The general health progressively deteriorated, and after about nine months the patient became confined to bed. Eight days before death sugar appeared in the urine, and remained present until the fatal termination. Thus a transformation from diabetes insipidus to mellitus took place. At autopsy, amongst other lesions, the pancreas was found to be atrophied, and small metastic growths were found in the right suprarenal capsule. The uterus was entirely wanting, and it is supposed that the same had been previously removed on account of carcinoma. This fact, however, had been concealed by the patient. After considering several hypotheses to account for the diabetic condition and the transformation from the "insipid" to the "mellitus" form, the author concludes that the most reasonable supposition is that the same was dependent upon the carcinomatous growths.

French Journals.

Hypertrophy of the Tonsils.—Ed. Laval thinks that it would seem logical to treat in the same chapter of pathology hypertrophy of the tonsils and adenoid vegetations. These affections often occur in the same subject. Hypertrophied tonsils fall into two groups, clinically, viz., those which are greatly hypertrophied, and those which are enlarged to only a moderate degree. The very large tonsils may be either hard or soft. When the tonsils reach the size of a large hazel-nut they are generally hard. The only treatment of any avail in these cases is ablation. It should always be remembered that no operation is to be undertaken till the inflammation has disappeared. After the operation, only soft food should be taken for a week, as the wound must not be irritated. Although, as a rule, very large tonsils are firm, white, and sclerotic, now and then they are soft, congested, and red. In such cases the only treatment suitable is cauterization. In cases of moderate hypertrophy, treatment ought to begin with curettage. If this is not curative, cauterization ought to be tried. General treatment should always be resorted to, consisting in the administration of cod-liver oil, in exercise, and in open-air life.—*Bulletin Général de Thérapeutique*, January 15, 1902.

The Journal of Tropical Medicine, January 15, 1902.

The Best Method of Administering Quinine as a Preventive of Malarial Fever.—Edward Henry Read concludes from his experience that the best way of giving quinine as a prophylactic is the following: (1) For male adults in good health, tabloids in 15 gr. doses every fifth day; for those in poor health, the solution used in the same way, or 15 gr. powder in a tablespoonful of porridge or milk; (2) For female adults, 8 gr. should be given instead of 15; pregnant women may take 2½ gr. daily, in either of the above ways, from the beginning of pregnancy; (3) Children of either sex under one year, ½ gr. of the powder every third day in a spoonful of milk, followed by a spoonful of jam or honey; those from one to five years, 1 gr. every third day; from five to ten years, 2 gr. every third day; from ten to fifteen years, 3 gr.; above fifteen years, the ordinary adult dose, taken in the same way.

The Duration of the Latency of Malaria.—A. Sims believes, from observations and counts made at the Seamen's Hospital, that about 400 fully-grown parasites to the c.mm., or the presence of about two billion adult parasites in the body, is the lowest level of parasites to be borne without clinical symptoms. The duration of initial latency depends upon the number of transstellated sporozoites. Malignant tertian has the shortest latency, next tertian, and quartan the longest. As to latency after a first fever, the explanation of the period (always lengthening) between the attacks of fever is as follows: Each attack confers a temporary immunity; this is lost after the increasing periods mentioned, and the person regains immunity after the parasites have been killed down. There is no absolute limit to latency while a person is subject to reinfection, but there is a strong tendency for the infection to wear out. The interval is variable. Quinine taken in fever, or prophylactically, will help to keep the parasites at a low level, and therefore comparatively harmless. Plehn maintains that by giving half a gram every five days he has increased the apyrexial periods, or latency, to about twelve to fourteen months on an average, increased the possible length of service of officials, and lessened the frequency, intensity, and fatality of the febrile attacks.

Revue de Médecine, January 10, 1902.

Researches into the Nature of Tuberculosis and Its Bacillus.—I. Ferran holds that he has discovered a new bacillus, which he calls phthisiogenetu, because of its action, or spermigenetic, because it produces spermine, which he considers to be the true agent in the diffusion of tuberculosis. It can be cultivated without the use of a culture oven, and in any of the nourishing media used, which would account for the extreme diffusibility of tuberculosis. The author holds that tuberculosis is invariably preceded by parenchymatous or interstitial phlegmasia, and that, indeed, no tubercles ever form without this phlegmasia. Injections of dead cultures of the new bacillus confer immunity against the phlegmasia, and hence against tuberculosis. To obtain a truly antituberculous serum, animals must be hyperimmunized with tuberculous pus, all living bacilli in the pus having been destroyed. The serum thus obtained is positively tuberculous antitoxin.

Contribution to the Study of Nervous Troubles Due to Indigestion.—It is not of the habitual disorders following chronic dyspepsia that Ch. Féré writes, but of the episodical troubles occurring in different forms of indigestion. The eight cases which he reports are, briefly, the following: Syncope following indigestion; paralysis agitans and syncope; incoercible vomiting, anorexia, pain in various parts of the body; pain at the seat of an old fracture, occurring during indigestion; acroparæsthesia and motor impotence; acute delirium; infantile convulsions, slight asymmetry, contracture of the left leg cured by vomiting; general paralysis in a syphilitic patient, with local sweating, epileptic attacks, prostration and death following specific treatment. The author gives details of all the cases, and cites reports of other authors. Disorders occurring late and of a lasting nature may be attributed to an intoxication, but early and acute troubles, terminated brusquely by an evacuation of the bowels, are probably of reflex origin.

Scleroderma Without Arteritis.—D. Goldschmidt describes a case which was a typical one of diffuse scleroderma. Macro- and microscopic examination of the sympathetic and of many cutaneous nerves showed them to be perfectly normal. There was also an absence of vascular lesions, so that the theories of a nervous or vascular origin of scleroderma would not seem to hold good. The thyroid gland was normal, in opposition to the view that scleroderma is due to Basedow's disease. Various writers have suggested that the affection was connected with the extraordinary proliferation of connective tissue found in these cases, and the author states that the microscopic findings in his case bore out this view. But the origin of this proliferation is shrouded in darkness. The author is inclined to think that scleroderma is due to bacterial infection. The action of a toxic agent would account for the variations found in the localization of the lesions in different cases, for this is characteristic of infectious diseases, as toxins do not always affect the same organs, but usually attack those which are in some way weakened. Several of the data in the case reported seem to point to an infection of some kind.

Febris Innominata.—J. H. Preston gives this name to a group of fever cases, fifteen in number, occurring in Tennessee, none of which had any of the clinical signs of typhoid fever, except the continued temperature, which did not follow the cyclic course of typhoid. None of these patients had diarrhœa, tympanites, or rose spots; neither did any of them have delirium or any great nervousness, and all of them recovered except one, whose fever ran fifty-two days. None had the prostration and muscular tremor, or subsultus tendinum, observed in typhoid fever. Neither was there a red or brown and dry tongue at any time present. In other cases of the same type the author has noticed in fatal instances what seemed to be a striking difference in the manner of approaching dissolution. In typhoid fever there is greater prostration, the patient seems to pass away without knowing or caring whither he goes, a peaceful termination of his long-continued state of lethargy, unless he dies from intestinal perforation and resultant peritonitis. But in nearly all deaths seen in the class of fever under consideration, there has been a clear mind up to death's door, with a watchful and anxious interest by the patient in the outcome of his case, with the frequent query, "When will I get well?" etc., and at the last there is a great restlessness that it seems impossible to quiet by any means whatever. The author says he has never been able to explain the condition, unless it be that the nervous system had succumbed to the intoxication to such a degree that it was impossible to get further elimination, because the patient does not seem to die from asthenia, but is simply overcome by something. From the paper it does not appear that the Widal test was employed.—*Memphis Medical Monthly.*

Enlargement of Bronchial Glands in Children.—D. McM. Officer calls attention to the large number of children who are affected with enlarged bronchial glands, which are so often the starting point of tuberculosis. In the diagnosis of the condition, if it be found that there is definite enlargement which persists for more than a fortnight or so, it should be assumed in the majority of cases that it is tuberculous, and the patient should be treated by open air, forced feeding, careful attention to hygiene, and guaiacol, and cod-liver oil internally. For the spasmodic jerky cough, the author uses thirty drops of creosote, with or without menthol, burnt on a hot shovel in the patient's room at night. At any time during treatment, sudden dissemination may take place, such as pulmonary infection, or even a general tuberculosis. Caseous glands have been known to rupture into a bronchus, with perhaps immediate suffocation from caseous material aspirated, or by hemorrhage into the bronchial tube. The author pleads for early recognition of a pathological process which has been largely overlooked in children, and which has an important and lasting effect on their lives.—*Intercolonial Medical Journal of Australasia.*

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION

Stated Meeting, held January [illegible], 1902

Parker Syms, M.D., President

Primary Sarcoma of the Pancreas.—Dr [illegible] presented a specimen of primary sarcoma of the tail of the pancreas, taken from a patient who had been operated upon by Dr M S Kakels. This was the third case of the kind on record. The patient was a woman, fifty-three years of age, and the operation was done with the expectation of finding a tumor of the left kidney. The tumor was found to be inoperable, and the abdomen was closed. The mesenteric lymph nodes were enlarged, but these were the only enlarged nodes in the body. The liver was enlarged, firm, and yellowish. The spleen was diminished in size, and its capsule wrinkled. The kidneys were also smaller than normal, and the cortex was irregular and mottled. There was a large, soft tumor in the tail of the pancreas, the surface of which presented firm nodules. These proved on microscopical examination to be lymph nodes incorporated in the growth. Sections were made from various parts of the tumor, the pancreas, the left kidney, and the spleen. The left kidney and spleen showed no involvement by the neoplasm. Although there was almost complete destruction of the pancreatic tissue, it was interesting to note that no sugar was found in the urine.

Dr M I Knapp referred to a case of tumor of the pancreas that had recently come under his observation.

Dr M S Kakels said that he had been able to find in the literature only twenty tumors of the body of the pancreas, and only four tumors involving the tail of this viscus. It was exceedingly difficult unless there was a palpable growth to make a diagnosis of tumor of the pancreas. This was well exemplified in the case under discussion, which he had diagnosticated as a sarcoma of the kidney, and had performed an exploratory laparotomy. The patient had been ill six months, and although the urine was repeatedly examined, no sugar was found in it at any time.

Diabetes Mellitus; Etiology and Pathogenesis.—Dr. C. E. Nammack read a paper on this subject, the opening one in a symposium on diabetes. (See page 256.)

Surgical Aspect of Diabetes.—Dr Arpad G Gerster was the author of this paper. He said that it was well known that dogs and rabbits, as compared with man, offer a remarkable immunity to infection by staphylococci; yet, when the pancreas was removed from these animals and experimental diabetes thus set up, the wounds rarely healed properly. In cultivating pyogenic bacteria, Theobald Smith of Boston found that these bacteria throve best in media containing between .2 and .5 per cent of sugar, a percentage almost exactly that found in the blood of diabetics. The surgical importance of the so-called latent stage of diabetes could hardly be too much emphasized. The products of faulty assimilation circulating in the blood of diabetics greatly devitalized the tissues, and led to a condition akin to premature senility, thus leaving the tissues especially susceptible to the invasion of microbes. While wounds generally healed kindly in most individuals, it was well known that all sorts of wounds in a few persons showed a tendency to suppurate. It was possible that these persons were the subjects of latent diabetes, or were in a condition which would eventually lead to diabetes. Furunculosis and carbuncle were relatively very common in diabetics. When excessive sweating and furunculosis were found in diabetics, one would usually be able to detect sugar in the perspiration. Furuncles and carbuncles were most commonly observed in middle-aged persons having glycosuria—in other words, in persons who were not very ill and did not live on a restricted diet. The favorite location for carbuncle was on the [illegible]. He had seen in a diabetic an enormous carbuncle extending from the [illegible] to the [illegible]. Early free, multiple incisions were demanded in these cases of carbuncle. Diabetic gangrene followed various slight traumatisms. Under almost any mildly antiseptic application the necrosed layer would be thrown off and cicatrization would soon take place. If, however, the primary lesion became infected there might result a more extensive and ill-conditioned ulceration. The treatment should consist of measures directed toward improving the local circulation. The perforating ulcer of the foot seen in diabetics did not differ from that observed in other persons, except for the tendency to lymphangitis and phlegmonous inflammation. For obvious reasons, gangrene of a whole extremity was seven times more frequent in the lower than in the upper extremities. In the non-infectious form of gangrene the determining factor was to be found in the existing arteriosclerosis. An early sign of impending gangrene of the limb was the occurrence of numbness or a peculiar painful sensation coming on after remaining quiet for a short time, and disappearing again on moving about. This evanescent limping in a diabetic almost invariably pointed to the approach of gangrene. Gangrene of the extremities was about four times more frequent in men than in women. Nearly one-half of these patients succumbed, death often resulting directly from the occurrence of diabetic coma. In non-infectious cases of necrosis of the toes and of the leg, when there was no fever, the limitation of the gangrene was to be sought for by an elevated posture and the maintenance of a dry state as long as possible. When the period of demarkation was well established, no operation should be undertaken without stringent necessity. Often a large part of a toe, or even a whole toe, would be cast off. The degree of arteriosclerosis present must guide the surgeon as to the point for amputation when this operation was indicated. In infectious cases another factor must be considered, *i. e.*, the necessity of avoiding contact, infection proceeding from the festering and gangrenous area. In such cases the surgeon was often forced to perform a high amputation.

Dangers of Operations on Diabetics.—The first danger in operating upon diabetics was from the anæsthetic. The next was the supervention of diabetic coma. The surgeon should scrupulously avoid infection, and be careful not to starve the patient by waiting until the afternoon before doing the operation. The operation should be performed in the morning after the usual physiological fasting of the night. Before and after the anæsthesia, the patient should be given two drachms of bicarbonate of soda and ten grains of the bicarbonate of potassium. It had been proposed to operate on diabetics under local or infiltration anæsthesia, but Fritz Grossman had observed a special tendency to diabetic coma after cataract operations done under cocaine anæsthesia. In amputations on diabetics the best results would be obtained from the use of short flaps and an open wound.

Prognosis.—The speaker said that the experience of all surgeons, his own included, indicated that more than one-half of the patients dying in diabetic coma had only moderate quantities of sugar in the urine. The main factor in the prognosis was, therefore, not the quantity of sugar in the urine, but the degree of acidity of the blood. The records of the Mount Sinai Hospital for the last ten years showed thirteen cases of major amputation in cases of advanced diabetes. Five of these died in coma within three or four days after the operation, and three others died some months later of coma, but apparently there was here no connection between the coma and the operation.

Diabetic Affections of the Eye.—Dr S Busby Allen took up this subject. He said that one of the earlier symptoms of diabetes involving the eye was a loss of power of the ocular muscles. The muscles innervated by the third nerve were the ones most often affected. These paralyses were generally partial, and sometimes disappeared, only to return after a time. They bore no constant relation to the severity of the disease. Paresis of the accommodation usually occurred early, and was partial. If occurring in a person under thirty-five years of age, and progressing rapidly, it should lead to the suspicion of glycosuria. There was no marked difference in the appearance of a diabetic cataract and an ordinary senile cataract. Of course, cataract occurring in very young persons, ripening within a few weeks and appearing simultaneously in both eyes, would be almost certainly diagnosed as diabetic; but in those of middle age the progress was slower, and the diagnosis could hardly be made without examination of the urine. Diabetes was the only toxic disease which produced cataract, but no hypothesis had yet been advanced which would satisfactorily explain this fact. The retinitis of Bright's disease resembled very closely the retinitis of diabetics, and the two were often associated. In diabetic retinitis the papilla was not usually affected, but there was an optic retinitis due to glycosuria. It was an early complication, and was one of the causes of diabetic amblyopia, a grave symptom, often a precursor of diabetic coma. A complete loss of vision was very rare, but there would be a central scotoma, particularly for red and green. This amblyopia resembled in all respects that produced by the excessive use of tobacco or alcohol. In operating for cataract in diabetics, the operation should be done at a time when there was a lull in the disease. A simple ulcer of the cornea in diabetes, as in nephritis, might lead to the speedy loss of the eye.

Prognosis and Treatment of Diabetes.—Dr. ABRAHAM MAYER discussed this part of the subject. He said that the prognosis of diabetes depended upon the degree of disturbance of metabolism. When the disease began in a severe form with the abundant formation of acetone, the prognosis was bad. When there was a good tolerance for carbohydrates, the prognosis was better. The more advanced the age of the patient at the commencement of the disease, the more favorable was the prognosis. Such complications as tuberculosis and gangrene were decidedly unfavorable. So also when arteriosclerosis complicated the disease. More favorable was the traumatic or syphilitic origin of the disease. Briefly stated, the following were the favorable symptoms: (1) Advanced age at the commencement of the disease; (2) Long duration of the disease without serious complications or much wasting; (3) Traumatic or syphilitic origin; (4) Freedom from the disease in other members of the family; (5) The occurrence of the disease in connection with obesity, the uric-acid diathesis and gout; (6) The existence of a mild form of glycosuria with fair tolerance for carbohydrates; (7) Rapid excretion of sugar with increasing tolerance for carbohydrates; (8) Favorable conditions of life, allowing of thorough dietetic and hygienic regimen, and (9) The occurrence of the disease about the time of the menopause. The unfavorable symptoms were: (1) Development early in life; (2) Early loss of flesh and strength; (3) Severe gastrointestinal symptoms; (4) The occurrence of diabetic gangrene; (5) The occurrence of the disease in other members of the family; (6) Phthisis as a complication, especially with a cessation of the glycosuria; (7) Large excretion of acetone and increase of ammonia; (8) Unfavorable conditions of life, and (9) Organic disease of the pancreas.

Treatment.—To-day, the speaker declared, the diet of a diabetic could be made so varied and palatable that the majority of these patients were content to remain on the proper diet. When syphilis or neurasthenia was the cause, special treatment for these conditions would be instituted. Our chief aim, however, should be to increase the power of the system to assimilate carbohydrates. No method which excluded dietetic treatment was of any avail. He was a believer in the efficacy of medicines in disease; to the dietetic management they were important adjuncts. The patient should be placed at first upon a rigid diet. It contained albumin, fats, and a very little alcohol. If the disease were in a mild form, the patient would become sugar-free in the course of a few days. In the more severe forms, it might be necessary to reduce the nitrogenous elements of the food. In the very severe form it was possible for the organism to produce sugar from its own elements. There were two axioms worth remembering, viz.: (1) When a weakened function is rested, it recuperates and regains its original normal condition, and (2) Overtaxation of a weakened function produces a permanent diseased condition. Thus, when the diabetic continued to excrete sugar for some time, the function became permanent, and his tolerance for carbohydrates was diminished. Again, if a diabetic were kept sugar-free for a considerable time by a strict diet, it would be found that tolerance for carbohydrates rapidly increased. According to his experience, diabetics, when on a restricted diet, suffered most from the exclusion of bread. He had found that some diabetics were greatly pleased by giving them walnuts in place of bread. From 100 to 150 grams of bread were equal to 90 or 100 grams of milk. The diabetic patient's mind should be kept at rest, and his surroundings made as cheerful as possible. He should be warmly clad. Sea baths should not be taken, but carbonic-acid baths would be found very invigorating. In the mild forms of the disease, a journey to some of the spas, as, for example, Carlsbad, might be advised.

Medicinal Treatment.—That opium and its alkaloids had a beneficial effect on the thirst and on the patient's general condition could not be gainsaid. It improved the assimilation of food, allayed the nervous irritability, and the annoying pruritus. Half a grain should be given at first, three times a day, half an hour after meals, and this amount should be cautiously increased, the constipating effect being overcome by the use of cascara or rhubarb. There was a great tolerance for opium in diabetes. The solution of arsenite of bromine was often efficacious.

The Bacterial Theory of Diabetes.—Dr. MAYER said that some years ago he had propounded the bacterial theory of diabetes. The idea was that bacteria from the intestinal tract might easily infect the pancreas and give rise to such changes as might lead to glycosuria. Acting on this theory, he had administered certain bactericides, notably the bichloride of mercury. It should be given directly after meals with a large draught of water. This had given him better and more lasting results in suitable cases than any other medicinal treatment.

Dr. J. C. BIERWIRTH of Brooklyn said that he had been deeply interested in diabetes for a number of years. The name diabetes mellitus conveyed to one's mind a certain clinical picture—chiefly polyuria and an increased specific gravity of the urine. According to his personal experience, however, there were many cases of glycosuria in which there was no increase in the quantity of urine, and no increase in the specific gravity of this fluid. He had just seen a case in which only fifty-seven ounces of urine were excreted daily, and the specific gravity was 1,018, yet the urine contained 3 per cent. of sugar. This was particularly important to remember, for it was the practice of very many physicians to take the specific gravity of the urine, and if it were not above 1,020, they would not think of examining for sugar. These were the cases which the surgeon should be on the alert for, because they were liable to give him an unpleasant surprise in the shape of an unexpected development of a diabetic coma. He was not so sanguine as Dr. Mayer in regard to the treatment. When a case had reached that stage at which thirst and polyuria were present, and betaoxybutyric acid was present, there was very little that the physician could do; but a great deal could be accomplished if such cases came under treatment quite early. This presupposed an early diagnosis; and in order to make this, the physician should make it a rule to ask a new patient for the urine for twenty-four hours, and examine it for sugar.

Dr. James J. Walsh said that it had been found in a certain number of experimental cases that destruction of the suprarenal capsule had some relation to glycosuria, and a few cases had been reported in which there seemed to be such a connection in the human subject. He thought it probable that in the near future or twenty years we might be willing to admit at least the possibility of the contagiousness of diabetes. It was well to call attention to the fact that after Gerhardt's test was positive very few diabetics lived more than two years. A physician could hardly be expected to examine the urine of every patient, but when a young man came to him complaining of weakness, of the occurrence of fatigue on slight exertion, or of loss of sexual power, the physician should lose no time in examining the urine for sugar. These were the cases which usually showed little or no increase in the quantity or specific gravity of the urine.

Dr. N. E. Brill said that a year ago Dr. L. Opie of the Johns Hopkins Hospital showed a direct relationship between disease of the islands of Langerhans and diabetes, and asserted that when these islands were not affected, although the rest of the pancreas might be diseased, diabetes would not occur. Dr. E. Libman of New York, while studying the proportions of glucose in nutrient culture media, had discovered that when the percentage of sugar was the same as in diabetic blood, i.e., 2 to 4 per cent., the bacteria grown on such media immediately precipitated the peptones. This might indicate that bacteria abounding in the blood might precipitate the peptones, and account for the frequent occurrence of thromboses and furunculosis. The speaker said that he could not accept the rationale given by Dr. Mayer concerning the action of bactericides in diabetes, because it had not yet been substantiated by pathological research. There had never been a case reported in which suppuration of the pancreas had been followed by diabetes. Bichloride of mercury was certainly serviceable in some cases of diabetes, but so far as his experience had gone, only in the syphilitic cases of diabetes.

Dr. ALEXANDER LAMBERT said that as peptone was only found in the portal vein, he thought that the theory just propounded concerning the precipitation of peptones in the blood was purely fanciful.

Dr. E. MAYER asked for experience regarding the use of potatoes as a food for diabetics.

Dr. NAMMACK said that he had perhaps not laid sufficient stress upon the coexistence of arteriosclerosis. The general practitioner had been too prone in the past to be satisfied with determining the quantity of sugar in the urine, ignoring utterly the dangerous acids found in the urine in diabetes. He wished to emphasize the great value of muscular exercise as an adjuvant to other methods of treatment. He was in the habit of encouraging the taking of sufficient exercise by offering an additional ounce of French roll for every mile walked in the open air. The statistics that he had quoted showed that the supposed contagiousness of diabetes existed in only 1 per cent., and when one recalled the similar conditions under which the same members of a family lived, this factor hardly seemed to be of much importance. He was of the opinion that the use of potatoes in the dietary of the diabetic was a very dangerous practice.

Dr. A. MAYER said that exercise was imperative, but it should stop short of fatigue. He had found in a large number of cases that in very nearly 8 per cent. in which he had investigated the condition of husband and wife was diabetic. He was a firm believer in the contagiousness, and even the infectiousness, of diabetes. With regard to the use of potatoes it should be remembered that in 100 grams of potatoes, as 75 per cent. was made up of water, there was really very little carbohydrate present. In the cases of diabetes, in which there was apparently a bacterial origin, he was sure that the bichloride of mercury was of service.

NEW YORK ACADEMY OF MEDICINE

SECTION ON OBSTETRICS AND GYNECOLOGY

Stated Meeting, Held January 23, 1902

A. BROTHERS, M.D., CHAIRMAN

Interstitial Salpingitis and Sclerosis of the Tube.—Dr. A. H. GOELET presented a specimen of interstitial salpingitis, which had gone on to sclerosis of all of both tubes; also a specimen of cystic tumor of the left ovary. The patient had suffered for eight years from profuse hemorrhage, dysmenorrhea, pain in the back and in both ovarian regions. The operation was done on January 8.

Symposium on Deciduoma Malignum.—This was the special order for the evening.

Clinical Review.—Dr. LOUIS J. LADINSKI presented the opening paper, reporting a case and presenting the patient and specimen. Marchand, he said, in 1895, was the first to point out the epithelial structure of these tumors. Before this the opinion had prevailed that they were sarcomata, presumably of uterine connective-tissue origin. There were three principal theories regarding these tumors, viz., (1) That they originate from the uterine connective tissue; (2) That they are the result of malignant changes in the decidual cells; and (3) The theory, held by the majority of German writers, that they are the result of a proliferation of the epithelial layers covering the chorionic villi, hence were epitheliomata. The histology and pathology of the disease were still far from settled. In the light of our present knowledge the term "deciduoma malignum" seemed to be the best. The speaker said there could be no doubt that these cases had occurred much more frequently than the records showed, but had been entirely overlooked, or had been designated by other terms.

The case reported was that of a woman of nineteen, born in Austria, and married a year and a half. She had had one child in the spring of 1900. About the middle of July she began to complain of pain in the lower part of the abdomen. About the end of that month there was a hemorrhage, and an escape of clear fluid, tinged with blood. She then began to cough and expectorate bloody fluid. About this time a severe uterine hemorrhage occurred at night, and required tamponade of the uterus. Dr. Freedman, who was in attendance, removed half a pailful of hydatids. She was then sent to the hospital and was curetted, irrigated, and packed. She was discharged on August 23, 1901. She returned on September 5, complaining of pain over the uterus, and examination showed the uterus to be enlarged, and slight bleeding present. She was given ergot and tonics and was directed to take douches. Another curettage shortly afterward brought away very little. On the night of October 3 she was again seized with a severe uterine hemorrhage, and was sent to Dr. Ladinski's service at the Gouverneur Hospital. Examination showed the presence of bilateral ovarian cystomata, about the size of cocoanuts. The os was patulous, and there was moderate hemorrhage from the uterine cavity. The uterus was not soft as in subinvolution, but was hard like a hyperplastic uterus. On dilating the uterus, and making a digital exploration, the endometrium was found smooth except at the posterior wall near the left cornu. Here there was a small nodule, which could not be separated or lifted up from the endometrium. It was soft, friable, and spongy, and bled freely when touched. On manipulation, the finger easily broke through its surface. This examination confirmed Dr. Ladinski's provisional diagnosis of deciduoma malignum. The next day, under ether anæsthesia, he did an abdominal pan-hysterectomy, having first separated the cervix from the vagina. The patient made an uneventful recovery, and the cough had greatly improved since that time. Dr. F. M. Jeffries, the pathologist of the Polyclinic Hospital, reported that the uterine growth was of a deep red color and smooth surface, and that on vertical section through the growth and the endometrium, the former was found to have penetrated to nearly half the thickness of the uterine wall. In the uterine structures around the neoplasm was a small cell infiltration and other evidences of secondary inflammation.

Dr. Ladinski said that he had been able to collect from the literature 135 cases. Of this number, ten had been reported in this country, eight in England, and most of the remainder in Germany. Pregnancy was an absolute precursor of deciduoma malignum; it preceded the disease in all of the cases reported except in one doubtful one. In 128 cases in which the nature of the pregnancy was recorded, fifty-one followed hydatid mole pregnancies; forty-two followed abortion; twenty-eight followed labor at term; four followed premature labor, and three followed tubal pregnancies. It was probable that death of the embryo was the cause of hydatid mole, though Marchand rejected this view on the ground that if it were correct, mole pregnancies would be more frequent. From a microscopical study of eight hydatid moles, three of which were followed by deciduoma malignum, the conclusion was drawn that hydatid mole was not always a benign growth. Some recommended that if an atypical growth of epithelial cells were found there would be every reason to suspect malignancy, and hysterectomy should be done. In thirty-three cases of mole pregnancy, the average duration was four months, and malignant degeneration occurred most frequently when the mole pregnancy terminated in the fourth month—in other words, the average duration of such a pregnancy. It was evident, therefore, that the duration of a mole pregnancy bore no relation to the development of deciduoma malignum. The average age of the patients in 134 cases was thirty-two years, which differed materially from the average age of the development of ordinary malignant disease of the uterus. The largest number of cases occurred in women having two or three children, or in those having a very large number of pregnancies.

Symptomatology.—Hemorrhage was almost invariably present, and was usually the first symptom to attract attention. It appeared without apparent cause, and was very characteristic. The bleeding from a deciduoma malignum, moreover, did not respond to the usual means of treatment. The discharge was commonly bright fluid blood, though in the more advanced stages it was dark and of a foul odor. The uterus had been found enlarged in all cases, so much so that in a number of instances there was a suspicion of retained placenta. It was important to remember that the consistency of the uterus was that of chronic hyperplasia. The os was usually patulous. In the early stage of the disease there was anæmia, which was generally attributed to the loss of blood, though it was usually more intense than could be accounted for in this way. Metastases had been found in the lungs in forty-seven cases, in the vagina in forty, in the spleen in thirteen, in the kidneys in thirteen, in the ovaries in ten, in the intestines in eight, in the brain in seven, in the broad ligament in five, in the pleura in four, in the mesenteric glands in two, in the pancreas in two, in the heart, stomach, pelvic and lymphatic glands each in one case. The cough and bloody expectoration were important, and probably pointed to the occurrence of metastases in the lungs. In this disease, much more than in incipient carcinoma of the uterus, the microscopical examination should not be solely depended upon for the diagnosis. Particular attention should be paid to the clinical signs and symptoms. In every case of mole pregnancy, scrapings from the uterus should be examined microscopically at regular intervals subsequent to the removal of the mole. Owing to the patulous dilatation of the os, it was usually easy to make digital examinations of the uterus in these cases, and under these conditions the diagnosis could often be made by direct examination of the uterus before it could be determined by microscopical examination of the scrapings.

Prognosis.—Deciduoma malignum was the most fatal of all neoplasms, because of its rapid recurrence and the formation of metastases. In forty-seven cases death had resulted from metastases, and in twenty-one it had been caused by hemorrhage and exhaustion. The average duration of life after mole pregnancies was six months, after abortion five months, after labor at term, four months.

Treatment.—As soon as the diagnosis was made, the only treatment should be complete extirpation of the uterus. In every case of mole pregnancy the uterus should be emptied as soon as the diagnosis was made, and if microscopical examination pointed to malignancy, there should be no delay in resorting to hysterectomy.

Pathology.—Dr. Otto H. Schultze presented this subject by means of a series of photomicrographs projected on the screen. Photographs of normal tissue were first shown as a means of comparison with the pathological ones. The author discussed at length the various theories as to the origin of the syncytium. The theory of the maternal origin of the syncytium, he said, had been based upon observations on the placentæ of animals.

Dr. H. J. Boldt said that whereas a majority of those who had studied this subject maintained that deciduoma malignum was produced entirely by the products of conception, there were some very competent observers who had given good reasons for their belief that it originated from the maternal side. One case that he had himself observed, and which was supposed at first to be a placental polypus, showed nothing abnormal under the microscope. The hemorrhage having recurred in a short time, the uterine cavity was explored, a new growth found, and then the uterus extirpated. It was determined subsequently that this growth was a deciduoma malignum. In another case, first observed by him, and subsequently by Dr. Brothers, the hemorrhage was so profuse as to prevent microscopic examination being made at the time. The disease showed itself soon after an abortion, and the growth was looked upon as an unusual form of sarcoma. In some cases it was not at all easy to make the correct diagnosis by the microscope alone.

A Historical Case.—Dr. Brooks H. Wells referred to a case that had occurred in the practice of a well-known gynecologist of this city about a year and a half before Sanger had reported his first case to the Obstetrical Society at Leipsic. The patient, eight or nine weeks after a delivery at term, began to flow and to pass spongy masses from the vagina of a reddish-purple color. The case was thought to be one of retained placenta, and accordingly the uterus was thoroughly emptied, but this only caused a cessation of the bleeding for a few days. A week or two later, the woman was again bleeding and passing these spongy masses. The speaker said that happening to be in the laboratory when Dr. Charles Heitzmann was examining the tissue, Dr. Heitzmann remarked that it was something new to him, and that if he were asked to give it a name he would call it a "malignant deciduoma." Indeed, this was the diagnosis that he gave to the gynecologist; but the latter would not accept such a strange diagnosis, and in consequence the case had not been reported.

Dr. S. W. Bandler said that he saw no reason for pain being a prominent symptom in these cases, and as for the enlargement of the uterus and the patulousness of the os, these signs were not characteristic, but were a natural part of a condition associated with pregnancy. The large cells described by Dr. Schultze were possessed of a wonderful power of wandering, and for this reason they were often mistaken for decidual cells, though they had nothing to do with the decidua. A better name than deciduoma would be "chorioma." The syncytial cells, which grew into the capillaries, were at all times during pregnancy given off into the circulation, and were claimed by some to be the cause of the convulsions of eclampsia.

Book Reviews.

A MANUAL OF MEDICINE. Diseases of the Nervous System. Edited by W. H. ALLCHIN, M.D. London. Vol. III. New York: The Macmillan Co., 1901.

THIS small volume contains a brief résumé of diseases of the nervous system by nine British contributors, as follows: Bertram Abrahams, Walter Stacy Colman, James S. Collier, Joseph A. Ormerod, Charles S. Sherrington, Purves Stewart, James Taylor, William Aldren Turner, and [illegible]. The physiological introduction by Sherrington is exceptionally clear and concise, and the various clinical types of nervous diseases are accurately but briefly described. A novel feature not usually found in other similar works is the special chapter on medical ophthalmology by Taylor, in which conditions of the pupil and ocular fundus are described with reference to their special neurological bearings. The authors have successfully accomplished a task by no means easy, in placing before their readers an acceptable treatise on nervous diseases which seems to cover the entire subject, although in a very condensed manner. The book will satisfactorily serve its purpose as a manual for ready reference, and is a welcome addition to the various larger volumes on neurology published within the last few years.

A TEXTBOOK OF OBSTETRICS. By BARTON COOKE HIRST, M.D., Professor of Obstetrics in the University of Pennsylvania, Gynecologist to the Howard, the Orthopedic, and the Philadelphia Hospitals, etc. Third edition, thoroughly revised. Philadelphia and London: W. B. Saunders & Co., 1901.

THE subject-matter in this work is presented in seven parts, the general arrangement being as follows: Pregnancy, The Physiology and Management of Labor and of the Puerperium, the Mechanism of Labor, The Pathology of Labor, Pathology of the Puerperium, Obstetric Operations, The New-Born Infant. The present edition has been thoroughly revised, and much new material has been added, especially in those chapters dealing with diagnosis of pregnancy, the pathology of pregnancy, the pathology of labor, and obstetric operations. A striking feature of the book are the illustrations with which it is embellished, many of which are original. The text is as condensed as is compatible with clearness, it is comprehensive, its style is attractive, and it is thoroughly modern.

THE MENTAL STATE OF HYSTERICALS. A Study of Mental Stigmata and Mental Accidents. By PIERRE JANET, Litt.D., M.D. Translated by CAROLINE ROLLIN CORSON. 528 pages. New York and London: G. P. Putnam's Sons.

THIS book, which has been for some years familiar to students of neurology and psychology, will be welcomed in its English dress. The late Mrs. Corson, who translated the book, acquitted herself well of a difficult task. The first part of the book is taken up with a discussion of the mental stigmata of hysteria, e.g., the anæsthesias, the amnesias, the abulias, the motor disturbances, and the modifications of the character, while the second part treats of the mental accidents of hysteria. Under the latter caption are discussed (1) Suggestion and Subconscious Acts; (2) Fixed Ideas; (3) The Different Forms of Hysterical Attacks: Emotional Attacks, Clownism, Ecstasies, Automatism, Complete Attacks; (4) Somnambulism, and (5) Delirium. The volume concludes with a brief chapter on hysteria from a psychological point of view. In this chapter the author discusses (1) Hysteria as a Malady by Representation; (2) The Undoubling of the Personality; (3) The Retraction of the Field of Consciousness, and (4) Hysteria a Mental Malady. Thus it will be seen that the author gives himself free scope for the discussion of this interesting neurosis. The book does not purport to be a treatise on hysteria, and therefore it cannot be compared with the works of Pitres and of Gilles de la Tourette. Although the mental state of hysteria is discussed in such treatises, none of them go into the subject with the detail and thoroughness of Janet. Nothing that can be said in a brief review [illegible] so adequately as that of the author's [illegible] of hysteria. [illegible] a certain number of elementary phenomena, sensations and images cease to be perceived and appear suppressed by the personal perception; the result is a tendency to a complete and permanent division of the personality, to the formation of several groups independent of each other; these systems of psychological factors alternate one in the wake of the other or coexist; in fine, this lack of synthesis favors the formation of certain parasitic ideas which develop completely and in isolation under the shelter of the control of the personal consciousness, and which manifest themselves by the most varied disturbances, apparently only physical.

Janet's brief definition of hysteria may also be cited: Hysteria is a form of mental disintegration characterized by a tendency toward the permanent and complete undoubling of the personality.

The volume is well printed and bound attractively.

DAS WIRBELTIERBLUT IN MIKROKRYSTALLOGRAPHISCHER HINSICHT. Von Dr. med. [illegible]. Mit sechsundzwanzig in den Text gedruckten Abbildungen. Stuttgart: Verlag von Ferdinand Enke, 1901.

IN this brochure of [illegible] pages, the various forms of crystals which may be obtained from vertebrate blood are discussed. In addition to the well-known hæmin crystals of Teichmann, which are described at length, numerous other forms are of scientific and forensic interest. But no attempt has heretofore been made to collect the facts and bibliography of the subject in a single volume. In doing this, the author has filled a gap in the literature, and completed an important chapter in the growing subject of hæmology.

A TEXTBOOK OF DISEASES OF WOMEN. By CHARLES B. PENROSE, M.D., Ph.D. Formerly Professor of Gynecology in the University of Pennsylvania; Surgeon to the Gynecean Hospital, Philadelphia. With 221 illustrations. Fourth edition, revised. Philadelphia and London: W. B. Saunders & Co., 1901.

ONE feature of this work which is worthy of special commendation is the attempt in nearly all cases to present only one method of treatment for each disease. This plan prevents much confusion. Careful attention is given to the detailed description of the technique recommended in the various conditions described. The best teaching of the most modern gynecology is presented here, and, as a rule, all facts of anatomy, physiology, and pathology which can easily be found in the special textbooks on these subjects, have been omitted. Only in those cases in which such mention is necessary to make clear the subject under discussion, or when there are certain points in the pathology that are characteristic of the diseases which are described, have these facts been emphasized. The book deals with the general causes of diseases of women, methods of examination, diseases and malformations of the genital organs, and the technique of gynecological operations.

LA FAIBLESSE IRRITABLE SEXUELLE. PAR V. RENZA. Paris: A. Maloine, Éditeur, 1902.

THIS is a psycho-physiologico-medical study of sexual weakness and neurasthenia, giving a method which the author deems infallible of conquering for one's self by ordinary means at the command of all this most distressing condition. The brochure which details the method contains 112 pages of interest.

A TEXTBOOK OF EMBRYOLOGY for Students of Medicine. By JOHN CLEMENT HEISLER, M.D., Professor of Anatomy in the Medico-Chirurgical College, Philadelphia. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders & Co., 1901.

THE modern medical student at the very beginning of his study of medicine realizes how absolutely essential a knowledge of embryology is to him. If he is deficient in this branch, he will also soon realize how few books there are which are concise enough for convenient use, and still full enough for his need. Such a book we believe the present volume to be. A knowledge of embryology is a necessary introduction to a comprehensive understanding of the subject of anatomy. The chapter dealing with the deciduæ and the placenta has been rewritten for this edition, as well as the greater part of the description of the chorion, for the recent work on these subjects by Peters and Webster has practically changed the earlier views There is a valuable tabulated chronology of development appended to the text.

THE MEDICINAL PLANTS OF THE PHILIPPINES. By T. H. PARDO DE TAVERA, Doctor en Medicina de la Facultad de Paris, etc. Translated and revised by JEROME B. THOMAS, Jr., A.B., M.D., Captain and Assistant Surgeon U. S. V. Philadelphia: P. Blakiston's Son & Co., 1901.

THIS is a very timely and important contribution, coming as it does from one whose ability to do the work was recognized by a government commission. The author, himself a native, spent two years collecting data bearing upon the uses made by the Filipinos of their plants. Works already published have been largely consulted and drawn from. The author believes that native physicians would do well to employ many of their indigenous plants, which, he states, patients usually prefer to exotics. Instructions are given as to modes of procuring and preserving these drug-plants, which are not, as a rule, kept in the pharmacies. The translation of this work, which was originally written in 1892, has for its aim to facilitate the study of plants by medical officers stationed at small posts in the Philippines. With this end in view the plants have been more definitely described when possible, and the English name given. No attempt has been made to give a strictly modern botanical classification. As it stands, the work should prove useful and an incentive to further necessary study in a most promising field.

PHOTOTHERAPY. By Professor NIELS R. FINSEN, Copenhagen. Translated from the German edition, and with an Appendix on The Light Treatment of Lupus. By JAMES H. SEQUEIRA, M.D., Lond., M.R.C.P., Dermatological Assistant and Medical Officer in charge of the Light Department at the London Hospital. London: Edward Arnold, 1901.

THIS is a work of considerable interest at the present time, coming direct from the pen of one who has done so much to make the light treatment what it is. It is disappointing, however, in its brevity. There are three essays, one on "The Chemical Rays of Light and Smallpox," another on "Light as a Stimulant," and a third on "The Treatment of Lupus Vulgaris by Concentrated Chemical Rays." These were written in 1894-'95 and '97, respectively. The appendix by Sequeira contains but four printed pages and some illustrations. Seventy-nine pages of large print, exclusive of many good pictures, complete the volume. The subject would stand a work several times this size, and the "Finsen" treatment is worthy of being written fully to date.

A TRAVERS LA MÉDECINE. Par DOCTEUR H. GUIMBAIL, Paris. A. Maloine, Editeur, 1901.

A SERIES of short monographs, written under date between July 1, 1900, and June 15, 1901, and including, under twenty-one headings, a variety of topics, which are treated in an easy literary style.

THE RÖNTGEN RAYS IN MEDICINE AND SURGERY. As an Aid in Diagnosis and as a Therapeutic Agent. Designed for the Use of Practitioners and Students. By FRANCIS H. WILLIAMS, M.D. (Harv.), Graduate of the Massachusetts Institute of Technology, Visiting Physician at the Boston City Hospital, etc., etc. With 391 illustrations. New York: The Macmillan Company; London: Macmillan & Co., 1901.

IT is so comparatively early in the history of the x-ray that one would scarcely expect an exhaustive, finished and complete exposé of the subject at the present day. The rapid strides making in therapy alone would render any work only preliminary, or, as the author states, a "report of progress."

From the clear and interesting manner in which the writer has gone over every department of the subject, giving from first to last personal experience based upon years of practical work, it is safe to say that the task has been undertaken by one thoroughly competent, and brought to a most successful issue.

The author's experimental work dates back to 1896, and during the whole progress of the book's construction improvements in apparatus, methods, and practical application of a personal nature have been incorporated in the pages.

The therapy of the Röntgen ray is still in an experimental stage, and though many things point to its becoming useful in several directions, still the reports here reproduced are not over-convincing. Internal forms of cancer are not discussed, but for the external varieties the ray appears to succeed as well as the Finsen light. There is some repetition in different portions of the book, especially concerning directions in the use of apparatus and like matter. The table of 635 cancer cases on page 442, as it catches the eye, is apt to mislead until the text is carefully read to show that they have nothing to do with x-ray treatment.

Many of the photographs of cases are poor, giving an entirely inadequate idea of the lesions.

Two hundred and ninety pages are devoted to chest examinations, freely illustrated.

A chapter on x-rays in dentistry deals mostly with deformities of the jaw, etc. The 658 pages are filled with interesting data of all kinds pertaining to the subject, and any one engaged or interested in x-ray work can scarcely afford to be without the book. The publishers' part has been attractively done.

INTERNATIONAL CLINICS. A quarterly of clinical lectures and especially prepared articles. Edited by HENRY W. CATLETT, A.M., M.D., Philadelphia. Vol. III, Eleventh Series. Philadelphia: J. B. Lippincott Co., 1901.

AMONG the contributors here listed one finds such names as Abercrombie of Charing Cross, Bie of the Finsen Institute at Copenhagen, S. S. Cohen, Deaver, Edebohls, Eyre of Charing Cross, Fagan of St. Vincent's, Dublin; Jullien of the St. Louis, Paris; Landolt of Paris, Pick of Prague, Routh of London, and Withington of Boston.

These and other writers present an interesting series of articles on phototherapy, sera, spas, corningization, convulsions, heart disease, goiter, pancarditis, inebriety, nocturnal epilepsy, appendicitis, and numerous other diseases and their treatment.

The Finsen light treatment is illustrated with pictures of apparatus, with the light being applied, and portraits of patients before and after.

A very important subject is that discussed by Professor Jullien—"Gonorrhœa and Marriage." He regards gonorrhœa as one of the most serious pathological conditions that afflict the human race. Lilienthal has a fine illustration of gallstones in his excellent article on "Some Acute Affections of the Gall-bladder and Its Associated Ducts."

The papers are generally up to the high level established by this periodical.

THE STANDARD MEDICAL MANUAL. A Handbook of Practical Medicine. By ALFRED S. BURDICK, M.D., Editor of the *Medical Standard;* Junior Professor of Practice of Medicine, Illinois Medical College, etc., etc. Chicago: G. P. Engelhard & Company, 1901.

The author disclaims at the outstart any intention to have this work regarded as the standard. The name has been borrowed from the journal in whose management much of the material which constitutes the text has been gathered. Brief considerations upon etiology, pathology, and symptomatology are given, but especial stress is placed upon treatment. The work is "in large part a compilation," and the author's effort to present the facts in as few words as is consistent with reasonable clearness has been realized. The articles are arranged alphabetically, and minor ailments as well as severe diseases receive due recognition. An epitome of the national formulary has been reclassified according to the therapeutic theses. An appendix contains the usual tables of drugs, doses, poisons, etc.

DIAGNOSTIK DER HARNKRANKHEITEN. Von PROF. DR. C. POSNER in Berlin. Dritte Auflage. Berlin: August Hirschwald, 1902.

THIS third edition of Professor Posner's excellent work, presented as an introduction to the pathology of the urinary passages, comes eight years from the publication of the first.

In this interval important advances have been made in methods of diagnosis, and these are duly reflected in the present volume. There are fifty-four illustrations, and, as an appendix, there is presented a short symptomatology of the usual affections of the urinary organs.

The subject-matter is arranged in the form of ten lectures, and due attention has been paid to endoscopy, cystoscopy, and other advanced methods of exploration.

THE PHYSIOLOGICAL ACTION OF DRUGS. An Introduction to Practical Pharmacology. By M. S. PEMBREY, M.A., M.D., Joint Lecturer on Physiology in Guy's Hospital Medical School, and C. D. F. PHILLIPS, M.D., LL.D., Examiner in Materia Medica and Therapeutics in the University of Aberdeen, etc. London: Edward Arnold, 1901.

THIS is an elementary work of one hundred pages, describing experiments in such a way as to make them available for the student, and which are limited to such as can be performed upon a brainless frog. Nearly a hundred experiments are described with a great variety of drugs of importance in medicine, and charts are freely interspersed in illustration of the effects produced by injection.

At the end is a table comparing ordinary and lethal doses in the frog and in man. The work is one based which, upon original research, and from its practical nature, should be of value to all interested in the action of drugs.

THE PRACTICAL MEDICINE SERIES OF YEAR BOOKS. Under the General Editorial Charge of GUSTAVUS P. HEAD, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Vol. I. General Medicine. Edited by FRANK BILLINGS, M.S., M.D., Head of Medical Department and Dean of the Faculty of Rush Medical College, Chicago, with the Collaboration of S. C. STANTON, M.D. Chicago: The Year Book Publishers, Chicago, 1901.

This is the first of monthly issues to appear, to comprise ten volumes on the year's progress in medicine and surgery, and though the volume itself is creditable to the abstractors, the scheme does not appeal strongly to the reviewer.

A year book should be a year book, and not ten spread over the whole year. The quarterlies have been open to the objection that in wishing to refer to a subject it is pretty sure to be in the volume which has not yet come out. This objection is here intensified. Even the subject of medical progress is not complete in one volume, since one part is issued in October and the other in May.

The November issue is scheduled to review general surgery under the editorship of John B. Murphy. The list of editors contains well known names.

DIE CHRONISCHEN NIERENENTZÜNDUNGEN IN IHRER EINWIRKUNG AUF DIE BLUTFLÜSSIGKEIT UND DEREN BEHANDLUNG. Von PRIVAT DOCENT DR. H. STRAUSS, Assistent der III. Med. Universitätsklinik zu Berlin. Berlin: August Hirschwald, 1902.

THIS is an unbound volume of 159 pages, treating on the influence of chronic inflammatory states of the kidney upon the blood, based upon a number of experimental observations on blood-serum and transudates. The treatment is also considered. Details of observations and experiments are given, with tables and data carefully worked out, and the general impression is made of a most painstaking conscientious study of the questions involved. References to preceding work upon the same lines are numerous, indicating that in prosecuting his original research the author has paid due regard to the investigations already committed to literature, which the present contribution tends to enrich.

HANDBUCH DER PHYSIKALISCHEN THERAPIE. Herausgegeben von Dr. A. GOLDSCHEIDER, a. o. Professor in Berlin, und Dr. PAUL JACOB, Privat Docent in Berlin. Teil I, Band II. Leipzig: Verlag von Georg Thieme, 1901.

NEVER before in the history of medicine has it been possible to produce such extensive writings upon the purely physical aspects of treatment scientifically considered.

Many methods, in former years scarcely sanctioned or admitted worthy of serious consideration, are now placed upon a firm basis, with results which must carry conviction.

The present large octavo of 535 pages, profusely illustrated with 175 cuts, contains a wealth of information upon massage in all its aspects, gymnastics from many points of view, Swedish movements, mechanical orthopedy, electrotherapy, and treatment by light. The list of collaborators is long, and contains names known and respected in all quarters of the medical world. The editors may congratulate themselves on producing a work of such magnitude and practical worth dealing with methods which are often neglected and left to the irregular or non-qualified practitioners.

ETUDES SUR LA TUBERCULOSE ET SON TRAITEMENT. TUBERCULOSES CHIRURGICALE, PULMONAIRE, INTESTINALE. Par Le DOCTEUR G. P. CHROMILAS, Chirurgien Honoraire de L'Hôpital Peau à Paris. Paris: A. Maloine, Editeur, 1902.

THE author of this monograph has done a large amount of work in tuberculosis, especially surgical, and now presents some of his results, most of which have already been discussed in the Academy of Medicine at Paris. A large part of the present publication is given up to reports of cases of bone and joint tuberculosis, in the treatment of which no startling innovations have been carried out or suggested. The author's plan of treatment has been along the customary surgical lines, and in a number of cases he has employed various forms of injection treatment. The reported results have been comparatively favorable. The most interesting subject touched upon is the treatment of pulmonary tuberculosis by the instillation of remedies through the trachea by means of a specially constructed syringe. A number of clinical experiences are recorded, and the method of application is illustrated by diagrams. The results are too irregular and the cases too few for us to draw any definite conclusions. As is frequently the case in foreign publications, there is too much clinical detail, and the book contains matter of considerable interest.

KLINIK DER VERDAUUNGS-KRANKHEITEN. Von Prof. Dr. C. A. EWALD. III. Die Krankheiten des Darms und des Bauchfells. Berlin: Verlag von A. Hirschwald, 1902.

EWALD'S new volume, comprising the diseases of the intestines and peritoneum, belongs to the most important works of recent medical literature. As is well known, Ewald is the foremost pioneer and classical writer in the field of digestive disorders. His book on diseases of the stomach was the first to propagate the new ideas and the progress made in the management of pathologic conditions of this organ. The present work on the intestines is fully abreast with the previous book of this author on the stomach. Although describing in detail the various methods of examination of the fecal matter, microscopically, chemically, etc., Ewald does not believe in requiring the physician to do laborious and troublesome work unless there is sufficient reason for it. In most instances, Ewald remarks, inspection of the fecal matter gives as much light as the microscopic and chemic examination. "Appendicitis larvata," a special type of appendicitis first described by Ewald, is vividly detailed. No distinct attack of appendicitis is mentioned by the patient; he merely complains of abdominal pains, sometimes in the epigastric region, sometimes in the region of the navel, or in the left iliac region, either constantly or at intervals; the diagnosis of some gastric or intestinal trouble is made by the attending physician, but the applied remedies fail to respond. The examination of the appendicular region sometimes reveals an abnormally thickened appendix which clears the diagnosis, or if this is not the case, the diagnosis of "appendicitis larvata" can be made by exclusion. The operation of appendectomy accomplishes a complete cure, and thus demonstrates the former symptoms as having been due to the appendicitis. Ewald's work on the intestines is clearly and fluently written. It is not overburdened by unnecessary literature and therefore not cumbersome. It states the facts in a lucid manner. We do not doubt that every physician will delight in reading and studying Ewald's new book, and will certainly derive the greatest profit from it for himself and his patients.

RATIONAL HYDROTHERAPY. A Manual of the Physiological and Therapeutic Effects of Hydriatic Procedures, and the Technique of Their Application in the Treatment of Disease. By J. H. KELLOGG, M.D., Member of the British Gynecological Society, Superintendent of the Battle Creek (Mich.) Sanitarium, etc. 8vo, 1,193 pages. Philadelphia: The F. A. Davis Company, 1901.

THE promise indicated by the comprehensive title of this book has been amply fulfilled. The rational uses of water in disease find, in this goodly volume, thorough and painstaking exposition from every view point of the practitioner. Part I is devoted to the history and physiology of hydrotherapy. The American reader will scarcely accept the statement that "half a century ago we were much nearer the front of this line of progress than at the present time." The author's early training may be the causes of his strange confusion of hydropathy with hydrotherapy. *Hydropathy*, indeed, flourished to a considerable extent in America, and many institutions devoted to these measures were established here half a century ago. The medical profession knows too well that these "institutions" have been the curse and bane of rational hydrotherapy. Their "measures" were in the main crude, heroic, and empirical, and their quackery so estranged the profession that many years of such earnest labor as is recorded in this excellent treatise will be required to reinstate hydrotherapy.

In his history of hydrotherapy in America the author displays a marvelous indifference to the contributions of his contemporaries in this field.

Part II, containing an exposition of the general principles and therapeutic effects of hydriatic application and general rules for their practical employment, is a mine of valuable information for the beginner, as well as for the veteran, though it is somewhat too discursive. Part III describes the technique of hydrotherapy with excellent illustrations of each step and procedure. Many needless methods and subdivisions which have come down from the hydropath could be profitably omitted. Indeed, redundancy is the only fault of this book. By pruning among needless material (for instance, disquisitions on diet, massage, electricity, sun-bath formulæ for converting thermometer scales, etc.) and changing the large type and margins to those more customary in medical books, this ponderous volume could be reduced to less repellent size. A summary of experimental work, a copious index, and bibliography conclude this handsome book.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 1, 1902:

	Cases	Deaths.
Measles	891	34
Diphtheria and croup	333	55
Scarlet fever	337	31
Smallpox	61	10
Varicella	59	..
Tuberculosis	358	156
Typhoid fever	23	5
Cerebro-spinal meningitis	..	..

Note on Enema Rashes.—Commenting on the fact that enemas are often followed by rashes, Charles Bolton states that in January, 1901, he ordered in his hospital service soft soap, to be used for making the enemas in half the medical and surgical wards of the hospital, and hard yellow soap in the remaining half of the wards. This order continued in force for six months. During this period a total of 903 enemas was given to 500 patients, of these 407 soft-soap enemas being given to 234 patients, and 496 hard-soap enemas being given to 266 patients. In the latter series seventeen rashes resulted, but in the former series there was not a single rash. Enemas of pure water were not used, as it was considered that if soft-soap enemas did not cause a rash neither would water alone. Three hundred of the patients received only one enema each, the remaining 200 having from two to six each, and a few of the more chronic patients from twelve to fourteen each. Of the seventeen rashes never more than one occurred in the same person, and when more than one enema was given the rash followed the first, second, third, or fourth, but not the later ones. In one case, after a patient had received several soft-soap enemas, the mistake of giving him a hard soap enema was made, and a rash resulted. The medical and surgical diseases from which the patients were suffering had apparently no influence on the rashes, and the same remark may be made concerning the aperient employed. This was usually given the night before the administration of the enema, and consisted either of calomel, castor oil, or house medicine. All the rashes appeared on the day following the injection, and their duration was from one to three days. They consisted in each case of fine, thickly sown papules, which either gave rise to a coarsely punctate appearance, or fused together into well-defined patches, mixed with areas of simple erythema. In one case urticarial wheals were present. In some cases the whole body was more or less uniformly covered; in others the rash was chiefly apparent on the buttocks and extensor surfaces of the limbs, or on the trunk, especially at the sides —*Clinical Journal.*

An Apology for Bacteria.—Richard Travers Smith calls attention to the beneficent microbes and the part which they play in the economy of nature. In the first place, they act as scavengers, the processes called putrefaction, decomposition, fermentation, and decay being carried on in the main by bacteria. They have a part as purveyors of suitable food to the animal kingdom. Animals cannot exist without plants; plants cannot exist unless their stock of food in air, soil, and water is continually renewed. The sources of renewal are three—dead animals, dead plants, and the waste products of living animals and plants. The transformation of these complex bodies into a form simple enough to be used as food by plants is accomplished by bacteria. Bacteria also are agents in capturing free nitrogen from the atmosphere and transferring it to the food circulation, in keeping up the amount of carbon interchanged between living animals and living plants, and in restoring sulphur to plants, which has been taken from sulphuretted hydrogen gas during putrefaction of proteids. Bacteria probably contribute to the formation of soil by furnishing acids, which soften the surfaces of hard rocks; and coal is thought by some to be the result of bacterial action on vegetable matter under peculiar physical conditions. Some evolutionists even claim that man's remotest ancestors were bacteria. —*The Dublin Journal of Medical Science.*

The Treatment of Rawed Peritoneal Surfaces in Abdominal Operations.—J. Clarence Webster emphasizes the need for careful treatment of rawed peritoneal surfaces in order to prevent the formation of adhesions and intestinal obstructions. Small patches on the parietal peritoneum, the bladder, and the back of the broad ligaments may often be covered by loosening the peritoneum round them, and bringing the edges together with catgut. Similar surfaces on a mesentery may be quickly closed by a continuous suture. Areas of omentum, which have been freed from adhesions, should not be left free; but if slight, should be covered with neighboring healthy omentum, and, if extensive, ligatured near their base and cut away. Raw surfaces on the intestine may be covered by a continuous catgut suture when small. If large, a thin flap can be cut from the omentum and stitched to the raw surface with fine catgut. The gap in the omentum is easily closed with catgut. In very bad cases it may be advisable to resect the affected portion of the bowel. Small areas on the uterus can be covered by means of a running suture. If the patches are large or numerous, transplantation of grafts of peritoneum may be tried. Frequently the author has simply cauterized such surfaces so as to form a black char, the char acting as a protection and preventing adhesions.—*Chicago Medical Recorder.*

A Case of Acquired Hydronephrosis of Twenty-five Years' Duration.—C. O. Theinhaus reports the case of a man of fifty-two years, who for twenty-six years had felt a marked swelling in his left side under the margin of the ribs, which, growing slowly but constantly, at times gave rise to attacks of severe pain and discomfort. At the time of examination pus was found in the urine, and was increased by pressure on the tumor; the patient was emaciated to an extreme degree, had a slight evening rise of temperature, and his general condition was such as to leave little hope for recovery after a prolonged operation. The sac was sutured to the muscles and drainage resorted to, Sonian's incision being used because it avoids infection of large muscle areas by the bacteria in the pus sac. The patient left the hospital six weeks after the operation, having gained about fifteen pounds, with a small urinary fistula in the lumbar region, and was advised to re-enter later for nephrectomy if necessary.—*St. Paul Medical Journal.*

Cryoscopy of Hydrocele Fluid.—Oscar Marchetti describes the results of his examination of the fluid of hydrocele by means of cryoscopy, or determination of the osmotic pressure of liquids from their freezing point. This was found to be —0.57° as a minimum to —0.80° as a maximum, and is thus lower than that of the blood, which is —0.56°. It does not appear to be at all related to the length of duration of the affection to the physical qualities of the fluid, nor to the changes in the tunica vaginatis. It therefore gives no data of importance in regard to the development of the process, and is of no value in diagnosis, but merely of interest biologically, and as confirming the already known fact that any marked difference between the freezing point of an effusion and that of the blood indicates its probable inflammatory nature. This shows that serous membranes under pathological conditions can create and maintain a lack of static equilibrium between the fluids—blood and effusions—which they separate.—*Rivista Critica di Clinica Medica.*

Contribution to the Study of Laryngo-Tracheal Fistulæ.—Paolo Lombardo Pellegrino reports a case of this rare [illegible] The patient had attempted suicide [illegible] by cutting his throat, but had merely opened the larynx without cutting the large blood vessels. [illegible] a small fistula in the median region. [illegible] A laryngoscopic examination [illegible] of small size [illegible] of the larynx. An operation was performed, the walls of the fistulous tract freshened with the bistoury. A flap of mucous membrane and [illegible] on the larynx was fixed against the [illegible] so as to close it, and a complete cure followed.—*La [illegible] Medica.*

Stricture of the Urethra in a Female, Complicated with Enuresis, Dilatation of the Bladder, Ureters, and Kidneys.—The patient of L. B. Tuckerman was a girl of five years who had always suffered from enuresis. The breaking of preputial adhesions gave some relief. On one occasion she was suddenly attacked with pain in the loins, dysuria, blood in the urine, and distended bladder. Catheterization showed considerable resistance to passage at the proximal end of the urethra. The latter was gradually dilated, the chief resistance remaining at the neck of the bladder. The subsequent history of the case was one of continuous residual urine though the patient seemed to have good control over the bladder. A sudden increase of acute symptoms was followed by death. At post mortem the entire urinary tract was found to contain pus. The bladder was dilated with greatly thickened walls, and a small cavity containing pus existed within the bladder wall at the fundus. Both ureters were irregularly dilated throughout their whole extent, and likewise the pelvis of each kidney, the cavity encroaching on the substance of the organ itself. The child had suffered from much colic and constipation alternating with diarrhœa, and this was partly explained perhaps by an anomaly of the ascending mesocolon, which was continuous with the mesentery and allowed as free movement of the ascending colon as of the small intestine itself.—*Cleveland Medical Gazette.*

The Treatment of Pneumonia with Creosote.—H. W. Cummings commends this remedy, finding that of twenty consecutive cases (all ending in recovery) in fourteen the crisis occurred on the fifth day. He found also that after he began the use of creosote the fever did not run so high as usual, nor did it fall so suddenly at the end of the disease, as to leave the patient prostrated, accompanied by the profuse sweat, but rather that the fever declined more gradually. Only one patient showed any alarming symptoms at the crisis, and she had just recovered from a severe attack of grippe when taken with pneumonia. Thus she was quite weak at the beginning. Again, he found that the use of creosote lessened, to a great degree, the severity of the cough and pain, and his patients required but little medicine to produce rest or sleep. Not one ever vomited or suffered with nausea while the medicine was being administered. Cummings uses the carbonate of creosote, beginning with ten drops every three hours, and increasing the dose five drops daily until twenty or twenty-five drop doses are given for an adult. When the maximum dose is reached, he gives the remedy at longer intervals, say four to five hours. In all cases he uses strychnine as a stimulant, beginning with small doses during the second stage, and increasing the dose as the patient approaches the crisis.—*Texas Medical Journal.*

Is Astigmatism, Like Myopia, Ever Progressive?—George C. Pardee concludes from his researches in this line that astigmatism increases in a certain number of cases (not to be neglected as only sporadic). Just what causes this increase is not quite apparent. But it is not unreasonable to assume that the same cause which effected a different curvature in the different meridians of the cornea may cause a still further difference in the curvature in a membrane which, like the cornea, may be acted upon so readily by it. The increase in nearly all of the cases discussed in this paper took place at such ages as would *a priori* place the cornea under such conditions as would render it yielding to the forces that caused its astigmatism in the first place.—*Transactions of the Medical Society of California.*

Sleepy Grass.—Sleepy grass is found in New Mexico, Texas and Siberia. It is said to have strong narcotic properties, and with horses and sheep to cause sleep lasting for a considerable time.

Population of Canada.—The population of the province of Quebec is growing at the rate of 9 per cent. in every ten years, while that of Ontario is increasing only 2½ per cent. in the same time.

Parks of London.—The City of London keeps up ten parks. Epping Forest is the largest; it contains 5,552 acres. The smallest is St. Paul's Churchyard, one acre in extent.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended February 7, 1902:

SMALLPOX—UNITED STATES.

GONORRHŒAL INFECTION OF THE PROSTATE.*

By JOHN VAN DER POEL, M.D.,
NEW YORK.

LECTURER ON GENITO-URINARY DISEASES, UNIVERSITY, AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

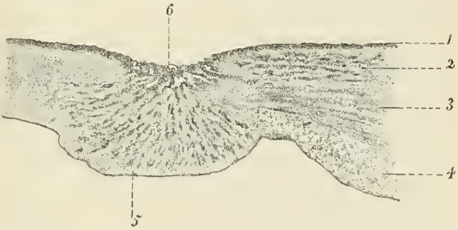
ALTHOUGH within a comparatively recent date, investigation and studies by genito-urinary surgeons have been particularly drawn toward gonorrhœal infection of the prostate, yet, due to its very frequent occurrence, inflammation of this organ has for years attracted the attention of medical men. Zeller, as early as 1700, and Littré and Warren, in 1711, were of the opinion that all gonorrhœas represented disease of this gland. Swediauer, in 1728, and Girtanner, in 1803, gave it as the cause of chronic clap, and the latter claimed that in most every case, acute or chronic, it was more or less involved; and that from that time on it constantly increased in volume and hardness, until the opening from the bladder was finally obstructed.

These ideas were later reiterated from time to time by various writers, until more recent studies have proven that prostatitis does occur as a complication of both acute and chronic gonorrhœal inflammation of the urethra, the result of a direct extension of the infection from its posterior part.

Anatomical studies show that the mucous membrane of the posterior urethra is in close connection with the prostate, and that it is but a short distance by way of the ducts to the glandular structure itself. Gonorrhœal inflammation of the posterior urethra, on account of these anatomical relations, unfortunately does not remain superficial or stationary; but the gonococci, advancing, penetrate rapidly into the prostatic glands, and sometimes into the parenchyma, as shown by Bumm, von Crippa, Finger, and others, and as the last says: "Exactly as they invade the glands of Littré and the lacunæ of Morgagni during the first days of an anterior urethritis, so in the posterior urethra they extend in all cases to the orifices in the prostatic urethra," *i. e.* the ejaculatory ducts, the prostatic utricle, and the openings of the glands lining the mucous membrane; for although these latter are not as abundant in the posterior as in the anterior urethra, where they are invariably involved in chronic inflammations of that part, yet they are present nevertheless in large numbers, as shown by Albarran, who had demonstrated two principal groups: one at the vesical neck, partly in the urethra and partly on the vesical trigone bordering on the neck (see Fig. 1 in cut), these not being constant, and one at about the middle of the prostate, at the veramontanum, opening into the urethra, or into the cavity of the prostatic utricle; and it is this latter group which, becoming infected, form a focus for extension directly into the prostate. The former, when involved, would seem to be the cause, or partly the cause, of increased desire to micturate, and play a prominent part in the etiology of hypertrophy of the middle lobe.

How far infection can take place through the vessels and lymphatics is, as yet, undetermined, though we know that a prostatitis can occur from a general infection (as in variola, shown by Guion; parotiditis by Güterbock, and pneumonia by Beck), although rare; as also through the lymphatics (as in rectal and perirectal inflammations).

Statistics as regards the frequency of posterior urethritis vary according to different observers: from one-sixth of all the cases by Leprovost to 93 per cent. by Dind. Finger states that in his experience it occurred more frequently in dispensary patients (82 per cent.) than in private practice (63 per cent.), but still less when patients were obliged to remain quiet in bed. Frank found it in about 33 per cent., and among 191 cases, dispensary and private, which I have observed within the past twelve months, it was present in seventy-six, or 39.7 per cent. This variance, as Finger mentions, is probably due to the different methods used in examination. The test known as the "Thompson two-glass test," where the patient is allowed to empty his bladder into two successive glasses, and where not only the first, but the second should contain cloudy urine, if the posterior urethra be affected, is not, in a large number of cases, sufficient, as a small amount of secretion may remain in the posterior urethra, and, not being sufficient to flow backward into the bladder, does not contaminate the whole amount passed; but remaining, would be washed out with the first gush of urine, as well as that of the anterior urethra; and not only this, but the first urine passed is sometimes not sufficient completely to wash out the anterior urethra, and part of its secretion may still be found in the second glass.



Still I think that, in the majority of cases, if most of the urine be passed in the first glass, and but the last few drachms in the second, where the bladder is at least moderately full, and that if this last should contain filaments or be cloudy, it is sufficient proof of a posterior urethritis, and will answer all practical purposes. However, at times it may be thought necessary to resort to the "irrigation test," the washing out of the anterior urethra as thoroughly as possible, before micturition, when, if threads or cloudiness are still present, the strong probability is that they came from the posterior part; or, perhaps as advised by some, to use a colored solution for this anterior washing, and to consider these threads not coming, as a rule, from the posterior urethra.

---

*Read before the New York State Medical Society, Albany, January 28, 1902.

The question as to how soon the infection reaches the posterior urethra is an important one, and to prevent, if possible, this extension should be our first indication in the management of acute cases, by destruction of the gonococcus at as early a date as possible, and there is reason, I think, to believe that this can be done in a number of cases.

The rapidity of extension would seem to depend upon, first, the virulence of a given infection, i.e., the strength and number of gonococci present, and, secondly, upon the quality of the urethral mucous membrane and tissues as a medium of culture. Usually it has been thought to occur not before the end of the second week or the beginning of the third. Finger, Ghon and Schlagenhaufer were unable to find it present before the sixteenth day in seventy infected cases. Hessler, in 1891, claims that among fifty cases, i.e., of posterior urethritis, he found it present in

[illegible] per cent. during the first week after infection
34 " " second " " "
14 " " third " " "
20 " " fourth " " "

Frank reports ninety-six out of 210 cases as early as the sixth day, and Bierhoff 21 per cent. within the first week and 38 per cent. within the first two weeks, though the latter's figures include a large number of Frank's cases. Among my seventy-six cases twenty occurred within the first week, i.e., 26 per cent., and of these, five were found on the fourth and one on the third day. The test accepted was cloudiness of the second urine, meaning the last few teaspoonfuls sometimes accompanied by frequent micturition, but more often not (phosphates and urates being excluded). Statistics as regards the occurrence of a posterior urethritis are apt, I think, to be somewhat misleading, as a number of cases will not only be found to have had previous gonorrheas, but a small percentage will give a history of previous posterior trouble, as shown by frequent micturition or epididymitis. Among my twenty cases occurring during the first week, nine had previously had one or more claps, and of these, one had had an epididymitis, and one a so-called "inflammation of the neck of the bladder," while several had had increased desire to urinate, the present attacks evidently being a reinfection or stirring up of the old seat of trouble.

The case which occurred on the third day, *i. e.* examined fifty-six hours after the first symptoms were noticed, was a first gonorrhœa with an incubation of two and one-half days, the patient being intelligent, and with no reason for disguising the facts. He at the same time had warts and a beginning adenitis in the groin, and gonococci were found in his prostatic secretion, a prostate evidently the seat of a previous simple glandular catarrh, as shown by rectal examination.

Granting, however, that posterior urethritis develops or is present in at least one-third of all cases, how often may we expect prostatic infection to follow or to accompany it? Sigmund, in 1858, thought that every case of clap of several weeks' duration was accompanied by a swollen prostate. Montagnon in 1885, and Erard, in 1880 gave 75 per cent. as the number involved, and for Finger every posterior urethritis without exception is accompanied by a prostatitis, while Frank's recent statistics go toward confirming this last opinion, where in 210 cases of posterior urethritis 100 per cent. of the prostates were diseased, though not all with gonorrhœa, gonococci being found 175 times, other bacteria twenty times, and aseptic secretion with leucocytes in the remainder. More recently Bierhoff again strengthens this idea in his 171 cases, in fifty-one of which it was a primary attack. As in a fair percentage of my cases intracellular gonococci were not found, though all had either extracellular diplococci or other bacteria, I am not as yet prepared to state that every case of gonorrhœal infection of the posterior urethra extends to the prostate.

Although without doubt the infection may, and does, reach the gland in fresh uncomplicated cases, without active cause other than the direct extension of the gonococcus, yet we know that, given an acute anterior urethritis, inflammation of the posterior part of the canal and hence prostatic infection is aided by a variety of active agents, such as excesses in coitus and alcohol, repeated seminal emissions, the eating or drinking of irritants, excessive exercise and bodily exertion, as bicycle and horseback riding, straining, jumping, etc., local irritants as the passage of a sound or catheter, or the too forcible injection of strong solutions. The class of cases, however, where no active cause can be assigned, but where the prostate in primary gonorrhœas becomes infected at an early date, is not a small one. Upon rectal examination, either one or several softened spots, or perhaps a general softening or doughy condition, will very probably be found, indicating a pre-existing state of simple glandular and follicular catarrh.

If these softened spots in a non-gonorrhœal case are massaged, the fluid expressed will be found to contain, besides the constituents of prostatic fluid, more or less epithelium and, as a rule, pus cells, demonstrating the presence of catarrhal foci. If there has been an inflamed or congested condition of the posterior part of the canal prior to infection, I think with Bierhoff that the gonorrhœal process is very apt to extend to this part, and thence to the prostate. Likewise in the prostate itself, as we must consider that a gonorrhœal prostatitis always succeeds to a posterior urethritis, though often in a mild form, a pre-existing congestion of that organ favors extension of the process, and much more so the presence of catarrhal inflammation, usually the result of excessive venery, masturbation, or withdrawal.

The Pathological Conditions, caused by gonorrhœal infection (best described by Ghon, Schlagenhaufer, Finger, Jadassohn and Albarran), consist in, first, the glandular catarrhal, second, the follicular, a variety of the catarrhal, third, the parenchymatous, simple or developing into abscess, fourth, the periprostatic phlegmon, and fifth, chronic prostatitis.

The first three forms are more closely concerned in the limits of this paper. They are not, as a rule, sharply defined, the one from the other, but are more or less intimately associated, one following the other, as the parenchymatous from the follicular, and the latter a complication of the glandular. These follicles or "pseudo-abscesses" of Jadassohn are either a sequence of a simple catarrh, or an infection of a pre-existing folliculitis, a diverticulum, or gland mouth, having become obstructed with mucus, pus, and epithelium, stagnation takes place within the gland of secretion which contains gonococci, and which increasing and being prevented from escaping, if left to itself without mechanical assistance, sometimes ruptures, either, according to Finger, through the natural opening, or near to it. This author reports a case of obliteration of the ejaculatory duct, caused by the cicatrix of one of these pseudo-abscesses. Sections made from the cadaver have shown gonococci not only within the cavities, but also in the surrounding tissue, showing a beginning parenchymatous inflammation, though this latter, according to Albarran, may occur primarily. When present, the parenchyma becomes infiltrated with leucocytes (Finger), and per rectum the gland is felt much enlarged, and may be, as shown by Velpeau and Sallemand, riddled with the pseudo-abscesses, thirty having been counted in one case post mortem.

The swelling may rapidly subside at the end of a week or ten days, or go on to abscess formation, point and empty in almost any direction; and, as we know, that into the urethra being the most frequent.

In the 114 cases given by Segond, there was recovery in seventy, death in thirty-four, and urinary fistula in ten. "Some recoveries end apparently in complete resolution, others in an induration which gradually leads to prostatic hypertrophy." (Finger). Periprostatic phlegmon is in eight cases out of ten consecutive to a prostatic lesion (Campenon), and, as a rule, non-separable from true prostatic abscess. It so generally involves the cellular tissues in the posterior and lower aspect of the organ that the term ordinarily implies inflammation of that particular part. Rectal examination is not satisfactory, a general swelling masking the true character of the trouble, which Albarran compares with periurethral septic inflammations, and in which he has demonstrated—at least in one case—the presence of an anaerobic bacillus.

Symptoms.—Gonorrhœal infection of the prostate may, in some cases, develop gradually, or be present in spite of the absence of subjective symptoms, and in spite of the clearness of the second portion or urine (Frank).

In the greater majority of cases, however, the signs and symptoms of a posterior urethritis are more or less marked, though often but slightly so, or so gradual in their onset that they may at first escape observation, with but a slight turbidity of the second urine, and accentuated, though not pressing, desire for micturition.

When well marked, when the second urine is decidedly cloudy and thready, with the desire for micturition frequent and urgent, with more or less strangury, and possibly some blood with the last urine, symptoms referable to the prostate, a sensation of weight, pain, and tension in the perinæum, with sensitiveness and pain upon digital pressure per rectum, are also apt to be present, though the prostate may or may not be enlarged, depending upon the degree of previous trouble. Other cases of a more powerful infection may commence with a chill and fever, with perhaps mechanical obstruction; a small stream, twisted or in drops, or even, perhaps, complete retention. This is associated with intense pain in the deep perineal and anal regions, exaggerated by the slightest movement, or by defecation or micturition. Rectal examination, which is painful even without touching the gland, shows the prostate much increased in size, elastic and tender. The seminal vesicles are also usually involved, and may be likewise tender and swollen. This acute condition can last for a week or longer, depending much upon the treatment, and then resolve and form the initial stage of a chronic prostatitis, or go on to suppuration, prostatic or periprostatic.

Diagnosis.—The lighter catarrhal, as well as parenchymatous, forms may, as said, escape observation, especially in the sub-acute and chronic varieties; a good rule, therefore, in all cases where the disease has reached these stages, as also in every case of acute posterior urethritis, is, first, to make a rectal exploration, and, secondly, an examination of the massaged fluid, as only in this way can we discover by the finding of pus cells and gonococci the true condition. As a rule, the gland will be found more or less changed even in the lighter forms, as there are, I think, but few prostates which have not been the seat of a previous simple catarrh, and where areas of softening, or even a generally soft surface, will not be found. If parenchymatous, there is usually uniform enlargement, though sometimes only unilateral. Especial care is necessary in examining for gonococci, that we may be sure that those found in the massaged fluid at the meatus are really from the prostate and not from the urethra; hence, before the examination is made, a thorough washing and irrigation of the meatus, anterior and posterior urethra, and bladder should be done, immediately after which the examination is made. Wiping out the posterior urethra with sterile cotton through an endoscopic tube, and collecting the expressed fluid as it exudes from the prostatic ducts, is probably a more accurate method, but in many cases not feasible, and I think scarcely necessary if we are careful to wash thoroughly.

In acute cases the gonococci are not, as a rule, difficult to find; but in long-standing cases or chronic trouble they may be, and repeated search is sometimes necessary before we are successful, especially in finding them intracellular, which is necessary for a diagnosis, unless Gramm's decolorizing stain is used, and until we have, after repeated search, been unable to demonstrate their presence, we are not, I think, justified in concluding that this part of the genito-urinary tract can be eliminated.

The ordinary methylene blue will in most instances be sufficient, but a better method, and one quite as simple, is that of first "fixing" the slide for 10-15 seconds in methyl alcohol (to which has been added a few grains of alcoholic eosin, if a double stain is preferred), which fixes the preparation without shrinkage of the leucocytes, as is the case when we "fix" by heat over the spirit lamp; and then either the ordinary methylene blue or Goldhorn's polychrome methylene blue may be used. The body of the pus cell is thus stained a pinkish hue, while the pus nuclei and gonococci are stained blue or purplish. In doubtful cases it will be necessary to resort to Gram's method of decolorizing. That gonococci may remain dormant in the prostate for years is shown by Frank's case, where five years after marriage a wife, without previous trouble, became infected, and where no urethral discharge could be found in the husband; but where, after careful massage of the prostate, gonococci were found in the massaged fluid.

When preparing a slide or cover-glass for examination, it is important to remember not to express the fluid from the meatus or urethra, as by so doing gonococci, which may be contained in the urethral glands or lacunæ, might be dislodged. Sometimes, and not infrequently, the expressed fluid flows into the bladder instead of through the cut-off muscle; in this case, if the patient be allowed to pass the few drops of urine which have again collected, and this if necessary centrifuged, there will be no difficulty in securing sufficient for an examination.

After massage the irrigation should be repeated, to avoid possible further infection, or a re-infection of the urethra in chronic cases where there is no longer any urethral discharge. The presence of many leucocytes in the massaged fluid is evidence of a prostatitis and seminal vesiculitis, even where the bacteriological examination is negative (Frank); other bacteria which may be found, such as staphylococci or colon bacilli, are evidence of either a previous catarrhal trouble, or of a so-called "secondary infection" in a subacute or chronic case, which condition may persist for years, and may be the cause of sterility.

Treatment.—As all modern treatment of urethritis, acute or chronic, anterior or posterior, together with their complications, depends upon the presence or abortive procedures, all our efforts, primarily at least, are directed toward the extermination of the germ; therefore the constant and daily control by microscopical examination must be regarded as a *sine qua non*, if our cases are to be handled intelligently and successfully. I would apologize for an observation of this character were it not a fact that but too few are prone to bear it in mind, and that but too many are satisfied with a once-established diagnosis of an anterior inflammation alone, if even then there are not many who still deem it either unnecessary or avoid it. But, as has recently been remarked, "it would be equally as useless and futile to attempt to control the management and treatment of gonorrhœa without the microscope as it would be in a case of pulmonary tuberculosis."

A diagnosis once made, therefore, the quicker we can cure or heal an anterior inflammation, the less the chances are for infection of the posterior urethra and the prostate; and if the extension backward can be prevented only in a certain number of cases, we can thereby at least diminish the frequency of prostatitis. Those who still place their faith in the older methods of treatment with internal medication by means of alkalies alone in the first stage with or without hand injections of astringents followed by the resins and hand injections in the later stages, are becoming fewer in number. Yet, on the other hand, it must be borne in mind that many of the so-called modern abortive methods of lavage have not, as a whole, resulted in the most brilliant successes, although they have certainly guided us in the right direction. Still, on account of non-success or failures, either from faulty technique, or from not seeing the patient sufficiently early, or from disagreeable experiences in the use of too strong solutions of the different remedies in vogue, or from complications overlooked which are impossible to cure without resorting to other measures, such as prostatic infection, from which, as a focus, from time to time, upon slight provocation, a fresh urethritis is set up, or, perhaps, because the older methods, being easier of application and less troublesome, many—we might say, conservative practitioners—have either abandoned or have been loath to employ the so-called radical methods. Still, my experience has led me to believe that, with the proper use of the modern gonococcidal remedies, we will be enabled to diminish the percentage of inflammations of the posterior urethra and prostate, and the unfortunate consequences which are so apt to follow. The list of drugs which have been used as injections is almost as long as the pharmacopœia itself (at first, vegetable substances, after which the metallic salts, the principal one of which, nitrate of silver, was used first in America by Johnston and Bartlett, and subsequently in Europe by Carmichael in 1818, and it was this drug which was first employed in an abortive sense, though in very strong solutions, however).

Bichloride of mercury, though in much prominence in recent years, was used as early as Hunter's time, in strengths of 1 to 600, but overlooked, and only again brought forward since the discovery of the bacterial nature of the disease, by Cameron in 1884, Van der Poel in 1886, and Brewer in 1887, in weak solutions of 1 to 20,000 to 1 to 60,000, but used by the two last experimenters in large quantities as irrigations, though into the anterior urethra only, and as an "abortive" treatment.

More recently permanganate of potassium has become very prominent, used in the same manner, at first by Reverdin in 1892 and then more thoroughly worked out and exploited by Janet in strengths of from 1 to 400 to 1 to 4,000. Janet, however, who irrigates directly into the bladder, though not at the commencement of the disease, does not claim that the drug directly destroys the gonococci, but rather causes a serous infiltration of the mucous membrane, and in this manner acting unfavorably upon it as a culture medium, causes the gonococci to die off. Subsequently, the newer silver salts, as argentamin, argonin, largin, protargol, and albargin have come into use and have had their trial with varying success. The results which I have obtained have been with protargol, but recent experiments with albargin have also been encouraging, although not so much so as with the former, a silver protein containing over 8 per cent. of silver. This is not, however, as stable a preparation as might be desired—at least that which has been put upon the market in this country; and it is therefore desirable that fresh solutions be frequently made, i.e., every forty-eight hours, a practical way being to make up a few ounces of a 10-per-cent. solution at a time, best dissolved in a small amount of glycerin before the water is added.

Care and gentleness in treatment are at all times necessary and important, and traumatism from too forcible injections is especially to be avoided. It is quite unnecessary that the meatus be tinged with any blood after the treatment is finished. Instruments or catheters should never be introduced into the urethra as long as a purulent discharge is present. The procedure which I have found to give the best results is as follows:

After the patient has been allowed to void his urine, nature's method of irrigation, the meatus is cleaned with a ¼ to ½ solution of protargol, that being the strength used in the irrigations, and then, best in the horizontal position, the anterior urethra is filled with a ½ or ¾ per cent. solution of cocaine, usually ten to fifteen grams being sufficient, which is held from three to five minutes.

In sub-acute and chronic cases the cocaine will not always be found necessary, but in acute trouble it is important to anæsthetize the mucous membrane on the face of the cut-off muscle as much as possible, to diminish the spasm of this muscle (which occurs when foreign bodies are introduced into the urethra), and thus avoid over-distention and traumatism. The protargol is then injected directly into the bladder, best by means of the large sterilizable urethral syringes holding about 150 grms., to which soft-rubber or porcelain tips can be attached. This, I think, is preferable to the irrigating apparatus, as with it we can much better manage the force necessary, the amount of pressure being under direct control of the finger or thumb. The amount used varies, as sometimes patients will complain of a full bladder with 200 grams, which sign, however, is not a good one to be guided by, as this sensation may be absent until the bladder becomes over-distended; usually from 200 to 400 grams are employed when the patient is allowed to void it.

This procedure is repeated but once in twenty-four hours, with no intermediate hand injections by the patient himself. Alkalies or salol are used internally when scalding is present, and the usual observations are made as regards rest, diet, and keeping the alimentary canal free, as a concentrated urine is irritating. If our efforts are to be successful in, so to speak, aborting the disease, upon the second day the discharge will not only be less in quantity, but the microscope will show fewer leucocytes and fewer gonococci; and upon the third day but few gonococci, sometimes none, and fewer leucocytes, with an increase in epithelia and mucus, in a discharge which is distinctly mucoid in character, and decidedly lessened in amount. Upon the fourth day (seventy-two hours after treatment has been commenced), no gonococci should be present, and but few leucocytes, sometimes with no apparent discharge at the meatus, when it is necessary to centrifuge the threads and flakes passed in the urine for examination.

Although the discharge may now have stopped, it is still desirable to continue the irrigations for several days longer, for although much less virulent, there is apt to be a recurrence. If this recurrence is of a true gonorrhœal nature, or if the discharge has still continued, our efforts have not been successful, though the same treatment is continued until we have the so-called "aseptic" stage, with no bacteria, or the stage of "secondary infection," with other cocci and extraneous bacilli. In case of secondary infection, the irrigations are changed to bichloride of mercury from 1 to 30,000 to 1 to 15,000, diminishing the strength as the discharge disappears, and this is to be remembered especially in the subacute and chronic types; but in these latter cases we will probably have to look deeper for the cause, namely, in the prostate; though in saying this I do not mean to exclude the soft infiltrations of the urethral mucous membrane, with involvement of the glands and lacunæ, where endoscopy and dilatation with the Kollmann dilator come into play, but where the same rules for irrigation apply. Should no bacteria be found, and the secretion be "aseptic," astringents are indicated, used in the same manner as nitrate of silver from 1 to 20,000 to 1 to 10,000, or the so-called "Ultzmann Solution" (one part each of carbolic acid, alum, and zinc sulphate to 1,000 parts of water).

In order that an abortive treatment be successful, certain conditions, however, are necessary: First, the disease must be limited to the anterior urethra, and, if possible, treatment should be instituted within the first twenty-four to forty-eight hours, as every hour after the onset lessens our chances of success. Second, there should be no infection of the paraurethral glands, as these cannot be reached by the solutions.

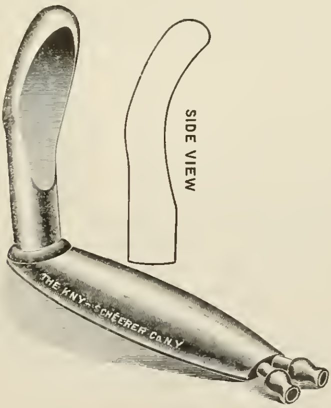
This—we might say—prophylaxis, as regards infection of the prostate, is not absolute, and does not always stop the progress of the disease sufficiently early to make the abortive principle a success, perhaps on account of too quick and deep an invasion of great virulence in non-resisting tissues; however, even though successful only in a certain number of cases, we are, I think, justified in making the attempt, and, not only this, but where the discharge has not been absolutely stopped within the time limit, the symptoms should run a much milder and shorter course, dryness not being infrequent within the first week; and when this happens, it is difficult to draw the line between such cases and those stopped at an earlier date, provided there is no posterior infection. Should the second portion of urine at any time become cloudy, should symptoms of prostatitis develop, or should this be present at the first examination, irrigations alone are not sufficient, as they do not reach the diseased gland, and other measures will be found necessary, *i. e.* massage of the prostate.

Instrumental massage is not to be recommended, as it is not only unnecessary, but dangerous, and the work can be much better and more intelligently accomplished with the finger. Gentleness should be remembered in all cases, the amount of pressure employed, varying; as a general rule, that in acute cases should always be lighter than when the trouble is chronic, and careless and unskilful work may quickly bring on other acute complications, such as epididymitis. Nevertheless, it should be complete, however gentle, until the affected part or parts have been emptied of their contents, following which the anterior, posterior urethra, and bladder are to be thoroughly irrigated with protargol, in the same manner as when treating the urethra alone.

Fever and tendency to pus formation are contraindications, and when present, all handling of the parts, excepting with the irrigations, should be avoided until either resolution has taken place, or the abscess has ruptured or been opened. In very acute cases, where the parts are hypersensitive, daily massage is inadvisable, every second or third day, according to the sensibility of the patient, being sufficient; and where we have a generally enlarged and painful prostate, indicating parenchymatous inflammation, with or without the small pseudo-abscesses, conservatism is the best policy.

As all parts of the prostate cannot be reached by the finger, especially in the anterior part and middle lobe, the use of the faradic current has been added and combined with the massage, by Hogge, Janet, Guiteras, Frank, and Freudenberg, that of Freudenberg being an arrangement by which the faradic current is passed through the finger of the operator as one pole, the hand at the same time being insulated. If the mouths of the glands and ducts have become plugged with inflammatory products and constricted by sursounding inflammation, the results of treatment will be less rapid. Rest, though always to be borne in mind as advisable, and in very acute cases as absolutely necessary, can be disregarded in the mild forms, excepting to guard against undue exertion or exercise. As to the application of heat or cold in acutely inflammatory conditions, I prefer the latter either by rectal douche, or better by the rectal cooler or psychrophore, once or twice in twenty-four hours, from ten to twenty minutes at a time.

Later, heat apparently acts better than cold, and in chronic cases, catarrhal or parenchymatous, especially those of a neurasthenic type, alternating heat and cold at the same sitting seem to act as the best stimuli to the circulation, combined with judicious massage. The instrument which I have recently employed for this purpose is a modification of that of Lewin of Berlin (shown at the last Naturforscher Versammlung in Hamburg). It can be used with the patient in a sitting posture, and can be controlled by him, the entrance and exit of the water when *in situ*, being in front of the perinæum and within easy reach.



ONE-HALF ACTUAL SIZE.

As regards the chance of epididymitis arising, either in connection with the irrigations or with the massage, one certainly gains the impression that it is of much less frequent occurrence than formerly, and even when it does occur during a course of treatment, it cannot, with any certainty or justice, be laid at the cost of the treatment itself. The frequency with which it occurs when no special method is mentioned varies from 7 per cent. (Gebert 1896) to 29.9 per cent. (Finger), though Finger's later statistics give 12.5 per cent. In 576 cases given by Le Fort, 264, or nearly one-half, had had no treatment whatever, and of the rest, seventy-three had only had balsams and no injections.

Among Frank's 651 cases of gonorrhœa treated with prolonged irrigations plus massage where prostatitis existed but 4.5 per cent. were affected. Among the 185 cases which I have treated with prolonged irrigations into the bladder including those where massage was likewise used when necessary, it occurred in but four after treatment was begun (i.e., 2.16 per cent.), but in twenty-three out of twenty-seven cases, irrespective of any form of treatment, it was present before the cases were seen. One cannot say that irrigations roughly given, or that massage roughly performed, will not lead to trouble; but when carefully and intelligently carried out, I am strongly of the opinion that epididymitis will be of much less frequent occurrence than when no local treatment whatever is employed.

The Prognosis of the lighter forms of gonorrhœal prostatitis is, as a rule, good; severe parenchymatous inflammation, however, may lead to such severe consequences that a guarded outlook is necessary.

The earlier a case is seen and treated, the less chance for extension and for involvement of the parenchyma and the less the chance for extension to the epididymis. True parenchymatous prostatitis is apt to be of long duration, and when there is abscess formation, as is well known, the point of rupture and involvement of neighboring tissues determine the danger of the case.

AN EIGHT-YEARS' EXPERIENCE IN THE RADICAL CURE OF MOVABLE RETROVERSIONS OF THE UTERUS BY ALEXANDER'S OPERATION.*

By LE ROY BROUN, M.D.,
NEW YORK.
ASSISTANT SURGEON WOMAN'S HOSPITAL

To bring before you such a trite subject should almost call for an apology. We are, however, all interested in this or any other method by which patients complaining of a certain common class of troubles can be relieved, and it is in this spirit that I bring this subject before you to-night.

It is a common experience to meet with patients, both single and married, who seek our assistance for relief from an almost constant backache, often associated with pain over one or both sides, and attended by some derangement of the menstrual function. A local examination frequently reveals a retroverted, heavy uterus, with no disease of the appendages. A further investigation may show that the uterus is not adherent, but can be replaced. When it is kept in position, the symptoms are relieved within a short time. If the patient is single, and the uterus refuses to remain in position, she shrinks from wearing a pessary and from the manipulation necessary for its after-care. If she is married and has borne children, there is frequently found a relaxed condition of the vulval orifice, preventing a proper fitting and keeping in place of the instrument. These two classes of patients are those of whom I wish especially to speak in this paper.

Local treatment alone gives only temporary relief. A well-fitting pessary, if desired by the patient, does relieve. These instruments, however, require a long practice attended by patience on the part of the physician and the woman, to enable one to adjust them properly so as to give the relief sought. When the pessary is not desired or is inapplicable, an operation of some character is to be chosen.

In my opinion the withdrawal of a portion of the round ligament of the uterus through the external abdominal ring (what is known as Alexander's operation) is preeminently the safest and best method to restore and retain an uncomplicated retrodisplaced uterus in its forward position.

Dr. Mathews of the Pathological Laboratory of the College of Physicians and Surgeons kindly made for me a microscopic section of the ligament, proving that it is made up of muscle bundles, and is preeminently fitted to retain the uterus in the position desired.

During the eight years ending January, 1900, there have been done on the service of Dr. Cleveland at the Woman's Hospital 230 of these operations. Of this number Dr. Cleveland has performed 109, the writer, 108, and the rest has been done by various house surgeons. Of this number there have been two deaths. In one there was a retroversion with adhesions. The abdomen was opened, adhesions severed, and Alexander's operation done. The patient died of septic peritonitis, which in no way could be charged to the character of the operation done except in so far as opening the abdomen would render such an occurrence possible. In the other, the operation was Alexander's, accompanied by some plastic work on the vagina. The cause of death was tetanus, after a duration of a few days. It occurred in January, 1895, at the time when there were three other cases of tetanus in the hospital, and of which we lost two.

In this particular instance the death was sudden and unexpected, I having seen the patient a half-hour before and found her pulse and temperature excellent. The supposed direct cause was an embolism. The condition of the wounds was excellent.

Neither of these deaths can be attributed to Alexander's operation, hence it can be fairly said that the death rate from this operation is nothing. In the words of Alexander himself, "I would as soon expect a death from an amputation of the finger."

When properly done, the union is invariably primary, and the anatomical and clinical result in my hands is all that the most sanguine operator could wish for.

It is sometimes a surprise to me to hear the varying opinions expressed concerning Alexander's operation, even at this late date, many have as their basis a lack of familiarity with the subject, and the class of cases for which it should be done; other adverse opinions are well grounded, yet in the light of my own experience I cannot but think they arise from contact with operations poorly done, and in many instances on improperly selected patients.

The chief field of this operation is for the correction of backward displacements of the uterus, associated with or without a coincident displacement of the adnexa. It is a prerequisite that the uterus shall be free of adhesions; can be easily replaced in its normal position, the bladder having previously been emptied, and that it shows no tendency to return to the malposition so long as the patient remains quiet upon her side on the examining table. If the adnexa of the uterus should have adhesions about them, and this condition be attended by a retroverted uterus, the patient will not be benefited by Alexander's operation unless these adhesions have been previously divided.

In this class of cases there will be found almost invariably adhesions existing between the uterus and the adjacent structures.

To one trained in pelvic examinations it is, however, in most instances an easy matter to determine the mobility or fixation of a backwardly displaced uterus, and to detect any abnormal condition of the appendages. If there is any doubt existing, especially in cases of fleshy women, recourse can be had to an examination under an anæsthetic, by which all doubtful points can be settled.

---

*Read before the West End Medical Society of New York City.

Such is the method of determining in each case whether Alexander's operation will be of benefit.

During the last eight years, having followed, as closely as it is possible to do, the after-results of this operation in all patients from our service at the Woman's Hospital, and being thoroughly conversant with the after-results of those in my private practice, I am convinced that in my hands no other operation for a like condition will yield the same constant anatomical result and the satisfactory clinical relief.

A backward malposition of the uterus is usually associated in multiparous women with a laceration of the cervix, and a tear in the floor of the vagina. There is also, as a result of the deranged circulation, an endometritis. A repair of the torn cervix and vaginal wall, together with the curettage, is done at the same time that the Alexander operation is performed, the order being curettage, repair of cervix, Alexander's operation, and repair of vaginal floor.

Technique of Operation.—After using various methods of doing this operation, each differing from one another in minute detail, the following course, as devised by myself in 1896, has been adhered to since this date, and has given a uniform anatomical result.

By this method the operation is changed from one of difficulty and uncertainty to one of perfect ease. and an absolute assurance of obtaining a large healthy ligament amply able to perform the function desired.

In my entire personal experience I have never found the ligament absent, nor have I found it emerging elsewhere than through the external abdominal ring.

The method is as follows: In the ordinary way, an incision of one inch to an inch and a half is made parallel to Poupart's ligament. The lower angle of the incision extends a fraction of an inch below the pubic spine and the greater length above.

This incision is continued rapidly through the skin and superficial layer of fat, no attention being given at the time to the capillary bleeding, which occasionally is quite free. If this does not stop within a few seconds under pressure, torsion is applied to the small vessels persisting in oozing.

The wound being dry, a portion of the tissue near the bottom is caught up with a pair of hemostatic forceps. A similar portion is picked up by another pair opposite to the one in place. By drawing on these very lightly, the intervening tissue is put on sufficient tension to divide it rapidly and easily with a sharp knife. The forceps in place act as light retractors, and while being thus used the tissue at the bottom of the now deeper wound is again caught up by a similar set placed opposite each other. The first pair applied are now removed, and the tissue between the second pair is divided as before.

Continuing in this way, each time applying the forceps deeper down, the tissues are rapidly divided throughout the length of the wound down to the aponeurosis of the external oblique. This is readily recognized by its glistening, large white fibers. During this dissection any persistent bleeding should be checked by torsion since the surrounding tissues will become stained and prevent a ready recognition of the aponeurosis. the desire being not to injure this in any way.

In the process of dissection I desire to call attention to the superficial fascia. This varies considerably in density, and is found midway between the aponeurosis of the external oblique and the skin. It is separated from the aponeurosis by a layer of fat of varying thickness. This fascia is the point of stumbling of most operators not thoroughly familiar with the operation. If the underlying fat is not abundant, the external ring can be easily felt through the thin layer. The operator cuts down on what he believes to be the fascia lying between the pillars of the ring. He is rewarded with the protrusion of the knuckle of fat so often spoken of. As he has been directed, he seizes this with his forceps, expecting to withdraw with it the ligament. He fails, and continues to search without success. He either gives it up or finds, after much search, his error.

This mistake may arise also from this overlying fascia being unusually dense, and resembling to a degree the aponeurosis. Especially is this possible when there has been free and obstinate oozing, coloring the surrounding tissue and preventing an accurate recognition of the layers.

The possibility of this error being borne in mind and avoided, the aponeurosis of the external oblique is exposed throughout the length of the wound. The side walls of the incision being lightly retracted, it is usual readily to recognize the external ring by its white pillars, the intervening space being filled in by a membrane (intercolumnar fascia) of a more delicate structure and hence darker shade. At times the pillars of the ring are so little separated, or the intercolumnar fascia is of such density, that to the eye there is no apparent ring. Here the sense of touch will often assist the operator.

First locating the spine of the pubis, or where it should be, with the finger, gentle pressure just above and beyond this locality will, in almost every instance, give at this point a slight feeling of weakness in the fascia. If this difference in resistance is not perceptible to the touch, a knowledge of the anatomical position of the ring above and obliquely to the other side of the spine is all that is necessary for an easy finding of the ligament. In this instance the small incision through the fascia should be made just beyond the spine, the cut being directed parallel to Poupart's ligament. The intercolumnar fascia, or the space between what should be the pillars of the ring, is cleanly cut through. The underlying structures are grasped with smooth-jawed forceps and drawn upward. While held in this position, the parts between the jaws of the forceps are separated from the adjacent parts by tearing aside the connective tissue.

At this stage there is almost always found, to the outer side of the tissue elevated by the forceps, the genital branch of the genito-crural nerve. If not here, it is within the tissue grasped by the forceps. Near this is the accompanying small vein. Care is taken not to injure this nerve, or to include it in the sutures to be afterwards placed. To accomplish this, it is isolated and temporarily held apart by the loop of a ligature.

The tissue between the jaws of the forceps, consisting of the round ligament and some fat, is grasped by the fingers, or a pair of smooth-jawed forceps, as the operator may fancy, and firm traction exerted. A few fibers of fascia become prominent by their thread-like tension. These are severed. In most cases the ligament is then readily withdrawn to the point of the cuff of the peritoneum, reflected over on it. This is stripped back until the ligament ceases to be withdrawn any further.

In cases where the ligament is not withdrawn with ease from the canal, the cause is due to some muscular fasciculi between the ligament and canal. By a continued steadily applied force to the end of the ligament these are broken up, and the desired length of about four inches obtained.

The pubic attachment of the ligament being now severed, two fine black silk sutures are passed each through one pillar of the ring, the ligament over the separated nerve, and through the corresponding piece of the other side. Before passing these sutures through the ligament, it is allowed to drop slightly back, the desire being to relieve the tension, and also to allow the peritoneal cuff that has been stripped back to retract into the general peritoneal cavity.

The ligament thus being under moderate tension, the suture nearest the internal ring is first gently tied. The ligament is then dropped and the remaining suture secured. The end of the ligament now projects through an opening in the external fascia, snugly surrounding but not constricting it.

This is dropped back in the wound, the floor of which is the external oblique aponeurosis. Before doing this, however, its distal end is surrounded and tied with a fine strand of gut to prevent an oozing which would color the surrounding tissues for some time unless prevented.

If the intervening fat between the aponeurosis and skin is of some depth, it is my custom to coapt the sides with a running suture of fine catgut, in order to obliterate dead spaces. This precaution is not, however, necessary in the majority of cases.

The skin is coapted by three or four fine black silk sutures.

A spica is snugly applied and not disturbed for forty-eight hours. The wounds are then dressed daily with sterile gauze. On the fifth or sixth day the skin sutures are removed.

The patient remains in bed for three weeks.

Anatomical Result.—The chief agents maintaining the uterus in its natural forward position are the utero-sacral ligaments and intra-abdominal pressure.

The utero-sacral ligaments, by their attachment, draw the lower segment of the uterus in a backward direction toward the sacrum. Thus it is that in vaginal examinations the finger comes first in contact with the anterior lip of the cervix. The body of the uterus, on account of the backward position of the cervix, now assumes a forward direction.

In this position intra-abdominal pressure (resulting from the erect position, breathing, etc.) is directed against the posterior wall of the uterus, pushing this organ still more forward, and with the utero-sacral ligaments maintaining it in this position. The broad ligaments and the included round ligaments act more as guys to the fundus of the uterus, preventing too great a motion backward. Especially is this true of the round ligament, which is made up largely of muscular tissue.

It is then reasonable to shorten these ligaments (take up the slack, so to speak), when it is desired to restore to an anterior position a uterus that has become displaced backward.

When the uterus is thus restored to a forward position, the intra-abdominal pressure and the utero-sacral ligaments are given an opportunity to exert their restraining influence, the former at once and the latter as soon as these ligaments have regained their tone. The broad ligaments also regain a tone that had been lost by the malposition of the uterus.

The object, then, of replacing and retaining a uterus in an anterior position by shortening the round ligaments is that, while thus placed, the anatomical structures, naturally holding this organ forward, are given an opportunity to regain their normal tone, after which they will exercise their natural functions. A striking example of this has recently come under my notice. It is as follows:

In February, 1898, a Mrs. H. came under my care for a retroverted adherent uterus. The abdomen was opened, the adhesions were divided, and a diseased right tube and ovary were removed. The round ligaments were then shortened through the external abdominal ring.

The patient consulted me last month, two years after the first operation, complaining of pain over the remaining ovary and tube. Upon examination a small ovarian cyst was found, the uterus was in excellent position. I removed this cyst two weeks ago. It was of much interest to note the condition of the round ligaments within the abdomen after this lapse of two years. They were under no tension. The uterus could be even pushed backward without causing much tension on these ligaments. When released the fundus would resume its anterior position. The uterus was plainly being held in its normal position by the utero-sacral ligaments that had regained their tone and by the guying influence of the round and broad ligaments.

I shall have occasion to refer to this most instructive case later in connection with the appearance of the tissues around the internal ring, immediately after the shortening of the ligaments at the first operation and their appearance two years after.

When the uterus is held forward by shortening the round ligaments, the correction of the malposition is thoroughly satisfactory. The uterus is brought to a forward position, not antiflexed, yet resting in a natural position, which, when the patient is standing, is made still more forward by the intra-abdominal pressure.

It is my custom after the ligaments are withdrawn for the usual length of four inches, to assure myself of the correct position of the uterus before proceeding with the operation. This is done by an assistant, catching the uterus between two fingers in the vagina and the other hand on the abdomen.

Preference is given to this method over that of the sound, since one can intelligently push back the intestines, which not infrequently obstruct the upward and forward motion of the fundus of the uterus by their presence above and in front of it.

Surgical Result.—As I have stated, the invariable result is now a primary union. The line scar of only an inch to an inch and a half is soon covered by the growth of hair natural to this locality, and within a few months can only be found under the closest inspection.

Suppuration, so often spoken of as a result of this operation, is a condition now rarely ever encountered. During the first three years of the time included in this paper suppuration did occur at times. Its occurrence is now directly traceable to the method of operating at that time, necessitating not infrequently a search for the ligament of considerable duration, and a laceration of the surrounding tissues in the process of locating and isolating it. I cannot urge too great a care in avoiding laceration of tissue in this operation.

The withdrawal of the ligament through a clean-cut incision will never be followed by suppuration, unless through septic ligatures.

Permanence of Result.—I have, wherever possible followed with care all of the 230 cases operated on at the Woman's Hospital, up to January, 1900, as also those done in my private practice.

I am aware of only one in which the uterus has resumed its backward position. In this instance the ligaments were anchored with chromicized catgut. A subsequent operation was done on this patient for appendicitis. The uterus was found to be free and the appendages healthy.

From this experience, and on account of the uncertain time that chromicized gut will remain intact, I have never used it in this operation since the above occurrence.

Sutures.—The suture preferred to fix the ligaments to the pillars of the ring, is fine black silk of the size ordinarily used for intestinal work. This should be freshly boiled, and allowed to remain covered by its boiled water until used.

Clinical Result.—The relief from symptoms following this operation is, in the large majority of cases most gratifying to the patient as well as the operator. The distressing bearing-down pain in the back ceases almost at once. The pain over the scars, so often complained of as following this operation, does not occur when the nerve emerging from the ring with the ligaments is carefully isolated and not included within the anchoring sutures. This has been done for the last five years.

Previous to this my custom was the same as that of other operators, to sever this nerve, since it interfered with the easy withdrawal of the ligament from the canal. I have only seen trouble arise from it in three instances, all of which were in thin women when the suprapubic fat was poorly developed. In each case its color rendered its removal very easy. I formerly used chromicized catgut. It was abandoned on account of the uncertainty of the length of time it would last. At present we are using kangaroo tendon through the ligament in place of the silk; the knots are, however, so large that I personally prefer the silk.

Separation and Preservation of the Nerve.—I regard this as a most important part of the operation.

Up to five years previous, my custom was to sever this nerve whenever it presented itself, the object being to permit the ligament to be easily drawn out. This was the accepted technique. We had, as others, not infrequently to face a more or less annoying pain over the cicatrix complained of by the patients. This pain was frequently obstinate. I became convinced that the pain was due to the severed nerve being caught in the cicatrix. Since adopting the method of separating it and placing it beneath the suture, the annoying neuralgia complained of has ceased to be noticeable.

Relation to Child-Bearing.—There is an enormous amount of statistics on this subject, and in no instance has there been reported any complication in pregnancy or delivery as the result of shortening of the round ligaments. As the uterus through the months of pregnancy enlarges in size, and the fundus ascends towards the diaphragm, the round ligaments keep pace and become larger, longer, and more vascular.

Being made up of the same involuntary character of muscular fibers as the uterus, it retracts with the uterus at the time of labor, and subsequently undergoes involution in connection with the uterus.

When pregnancy follows this operation, the same increase in size and length occurs, and the same subsequent retraction. The non-interference of this operation with the progress of pregnancy is beautifully illustrated in a unique case done by myself some time since.

In July, 1898, a Mrs. P. was brought to me by a member of this society. I was aware of her local condition, hence did not examine her as I should have done. The object of her visit was to arrange with me a day on which the Alexander operation could be done. When under ether and ready for the operation, it was seen that the patient was about two months pregnant, the uterus being retroverted in the hollow of the sacrum. Neither the patient, nor her physician, nor myself had suspected this condition.

After consultation, it was decided to shorten the round ligaments and omit the operation on the cervix and perineum for a later date. Two very vascular, thick ligaments were withdrawn with ease. They were almost a half of an inch in diameter, twice the size of a normal ligament, and abundantly supplied with blood vessels.

The pregnancy was uninterrupted and the confinement was normal. The uterus is now in excellent position. I will have occasion to refer again to this patient under a different head.

Hernia Following.—It is recognized that inguinal hernia does at times occur after this operation under certain conditions.

Among the first few operations, as done at the Woman's Hospital, I am aware of two such cases occurring. Since then, though having made every effort to keep in touch with all of the Alexander operations, there has come under my observation only one instance of this kind following work done by Dr. Cleveland or myself. The causes of hernia following this operation are twofold:

1. At the internal abdominal ring.
2. Some fault of operation at the external ring.

I regard that both of these causes, predisposing to hernia, can be controlled by the operator.

1. At the internal abdominal ring the round ligament passes into the inguinal canal. If the abdomen has been opened for any purpose, and at the same time the round ligaments shortened, the operator can note the following conditions about the peritoneal aspect of the internal ring. As this ligament is withdrawn from the canal, it will be observed that the peritoneum, transversalis fascia, and interposed layer of fat, form a series of small ridges (puckerings), arranged somewhat in a concentric manner closely around the internal round ligament as a center.

If this ring is of the ordinary natural size, these puckerings will encroach upon this opening, and really present a barrier to the formation of a hernia.

If, on the contrary, the ring is unusually large, these folds spoken of will, when the ligament is withdrawn to its fullest extent, be partly drawn into the gaping opening, causing a depression at this point of a slightly conic shape.

If now the peritoneal cuff along the ligament is stripped back as far as can be through the external ring, and the ligament afterward allowed to recede about a half of an inch within the canal, relieving thereby the tension, the depression spoken of as occurring over the internal ring will be obliterated, and in its place will occur the folds of fat and fascia mentioned above.

It will be readily seen from the above that the possibility of hernia, as far as the internal ring is concerned, is in proportion to the extra size of this opening. It is also seen that, to avoid the possibility of this condition, the ligament, after the peritoneal cuff is stripped back to the fullest extent, should be allowed to recede a short distance to obliterate this cup-shaped depression, and incidentally to relieve the tension on the fibers of the ligament. When thus allowed to recede, the large internal ring is reenforced by the puckerings of tissue round about it, and the tendency to hernia would be even less than existed before the operation.

2. *Faulty Operation at the External Ring.*—If the ligament is withdrawn from this opening through a clean-cut incision, and without injuring the aponeurosis of the external oblique, this opening is strengthened rather than weakened.

This is evident when we remember that the ligament in the canal forms adhesions with the surrounding walls, and at the external ring fills up the space between the pillars, becoming closely attached to these and the muscular floor.

On the contrary, if the operator is forced to continue a long search for the ligament, and in doing so, not only slit up the ring, but incised the underlying muscle, it is but reasonable to expect a hernia on account of the weakened walls and floor of the canal. Under such conditions the strength of the canal can only be restored by accurately bringing together in a separate manner the various layers.

If, during the isolation of the ligament, the pubic attachment of the ligament is unfortunately destroyed, or if the ligament is broken off in the canal when only partly withdrawn, either of which accidents rarely happens to me now, my custom is first to attempt to pick up the end from the canal. If this cannot be done without mutilating the surrounding tissues, I deem it better surgery to continue the incision beyond the internal ring and do a Bassini operation.

Size of the Ligament.—When the former method of operating by touch was in vogue, the ligament separated was occasionally so small as to be worthless for the purpose intended. Since the method devised by me in 1896 has been in use and the ligament has been isolated under the eye, the size has been constantly about one quarter of an inch in diameter, occasionally they are much larger.

The occasional worthlessly small ligaments of former years were only a portion, the other part being left in the canal.

Two months before preparing this paper for your society, I completed the operation on the patient mentioned before, on whom Alexander's operation was done while two months pregnant, the operation on the pelvic floor and cervix being left for this later date.

The local condition after this two-years' lapse of time was most instructive. The uterus was receiving no support from the vaginal column, since the pelvic floor had been badly torn in previous labors.

The position of the uterus was forward, but had fallen to a lower plane in the pelvis than that normally occupied. The round ligaments had retained the uterus in an anterior position unassisted throughout the involution following the confinement, and only through the lack of support from below had it sunk to a lower plane in the pelvis.

INTERMITTENT CLAUDICATION (INTERMITTENT LIMPING), DUE TO OBLITERATING ARTERITIS.*

By CHARLES L. DANA, M.D.,

PROFESSOR OF NERVOUS DISEASES, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK.

MRS. L., widow, aged seventy-eight years, was a patient of Dr. F. A. Burrall, and seen by me in consultation with him. Family history, negative. Father a very healthy, long-lived man, lived to be eighty-six years old. Previous history presents nothing of importance. She has been a healthy, active woman all her life up to within recent years. There is some tendency to gout in her family history and her personal history, but it is slight. She has one or two Heberden nodules on her fingers. Six years ago she had a slight attack of right hemiplegia. There was no shock or cerebral disturbance at the time, and she seemed to have recovered completely after a few months. Since then she has been reasonably well until her present illness came on.

One month before she was seen by me she had rather suddenly, during the daytime, a sensation of coldness in her left foot; this was combined with some objective coldness, and with some pain, stiffness, and weakness in that extremity. She went to bed, and was under the care of her physician, Dr. Burrall. During the succeeding weeks she complained of a good deal of pain and disagreeable sensory disturbances in the foot, especially along the back of the foot and up the anterior surface of the leg. The leg also was slightly swollen and weak, and she was able to walk a little, but was kept in bed. There was no other special disturbance and the right leg was not at all involved. At the end of a month the pain and a good deal of the coldness and swelling had gone. She was feeling nearly well, though the leg was still weak, when she noticed suddenly, during the day, a sensation of pricking and numbness of the left arm and hand. This also felt a little weaker and she had a slight pain in it.

She was seen by me on the following day in consultation with Dr. Burrall. I found her lying in bed and complaining of some pain and coldness in the left leg, and some numbness and weakness in the left arm. She was an active, well-nourished looking woman, well preserved for her age.

There was no sign of any paralysis of the face, nor was there any deviation of the tongue or any disturbance of the eyes or pupils. There was a slight trace of defective innervation of the right side of the face, a relic of her old hemiplegia. The fingers of her left hand felt cold and moist, but she did not feel any sensation of coldness herself. There was a very slight œdema of the arm. The grip of the left hand was forty and that of the right was fifty, showing some appreciable weakness. There was no disturbance of sensation objectively in the hand and no tenderness. The pulse in the left arm could not be felt either at the wrist, in the axilla, or at the elbow; the pulse in the right arm was easily distinguishable, rather full and rapid, being 90° F.

The left leg looked normal and was not swollen, though it had been. The power of the left leg was slightly diminished. There was no anæsthesia and no tenderness, nor did it look particularly different in color from the right leg. The knee-jerks on the right side were exaggerated, the plantar reflex of the right side was exaggerated and of the flexor type. The knee-jerk on the left leg was diminished and the plantar reflex absent. It was impossible to feel the pulse in the foot or the popliteal space on the left side, though the pulse was distinctly present in the right leg. There was no blueness or discoloration of any kind upon either extremity.

The heart was beating rapidly and without intermissions, there was a decided systolic bruit at the base. Carotid pulsations were distinctly felt on each side of the neck. There was already some improvement in the condition of the left arm over the previous twenty-four hours. The patient had no trouble with the rectum, bladder, or digestion. Urine was normal, low specific gravity, but no albumin or sugar.

The patient's general picture was that of a slight left hemiplegia with paresthesia of the arm and leg, and pallor and coldness and slight œdema of the part.

The diagnosis was a stoppage of the large arteries of the extremities, either by thrombosis or by spasm or both. The case appeared to me to belong among those described by Charcot, Erb, and other writers, as intermittent claudication.

The patient remained, as I am informed by Dr. Burrall, about the same for several days. She then suffered from nausea, became more depressed, and finally died in her sleep.

"Intermittent claudication," or limping, is a term first used by Charcot in 1854,[1] to describe a condition characterized by sudden pain, stiffness, and weakness in one leg, brought on by walking, and disappearing after a few minutes' rest to return when walking is resumed. His first patient was a man, fifty-four years old, who subsequently died, and was found to have an aneurysm of the iliac artery, which partly cut off the blood supply to the leg. He referred to the condition as a "paralysie douloureuse," and called attention to similar phenomena observed by veterinarians in horses (Bouley, Rademacher, Böther, and others), and dependent on an obliteration of the aorta or of the iliac or femoral. In 1886[2] he reported two other cases. In one of these the patient had for three months attacks of intermittent limping, followed ultimately by gangrene of the leg. In 1887[3] he reported another case in a man suffering from diabetes. In one of his cases post mortem showed an obliterating arteritis. Finally, in 1891,[4] he reported another case in a syphilitic. Further contributions were made by Sabourin in 1873, "Thèse de Paris;" by Delaunay in 1890, "Thèse de Paris;" by Magrez in 1892, "Thèse de Paris;" by Levet in 1894, "Thèse de Paris. The literature to date of other cases was given by Bourgeois in 1897, "Thèse de Paris." This included the description of a case involving the arm, reported by Nothnagel (*Berliner klinische Wochenschrift*, 1867, No. 51, p. 536).

---

*Read at meeting of Practitioners' Society, January 3, 1902.

In Germany, Goldflam first studied the subject exhaustively in an article entitled "Ueber Intermittent Hinken (Claudication intermittente Charcot's) in Arteritis der Beine." *Deutsche medizinische Wochenschrift* (Intermittent limping), 1895, No. 36.

The whole subject was again reviewed by Erb in an article entitled "Ueber das intermittente Hinken und andere Störungen in Folge von Gefässkrankheiten," *Deutsche Zeitschrift für Nervenheilkunde*, XII, 1898, p. 1; and Goldflam supplemented his first article with new cases and deductions in the *Neurologisches Centralblatt*, March 1, 1901, p. 197.*

There is a general agreement as to the characteristics of typical cases. The patient while walking is suddenly taken with pain, stiffness, weakness, and paresthesias of the leg. He is obliged to rest, and in fifteen or twenty minutes is able to walk again, but with a return of the symptoms. There are also vasomotor disturbances, associated with the condition, and the arteries of the foot, and often of the popliteal space, cannot be felt to pulsate. This latter is considered the diagnostic point. Erb examined the foot arteries (dorsalis pedis and posterior tibial) and found that pulsation could be felt in 99 per cent. of 700 patients, and Goldflam examined 200 with about the same result. There are variants from the ordinary type, in which the symptoms are not intermittent, and in which there it no paralysis, only paresthesias and vasomotor disturbances. The absence of the foot-pulse here determines the diagnosis.

While Charcot attributed the trouble more to disease of the large arterial trunks, Erb takes the view that it is usually an obliterative arteritis of the end arteries, and that vasomotor spasm is an element in causing the attacks. The trouble usually occurs in the later periods of life, and has been associated with exposure, diabetes, alcoholism, excessive use of tobacco (Erb), and syphilis. Goldflam, however, says that in his cases tobacco, syphilis, and alcoholism played little part, and that the malady occurs oftenest in neurotic persons. The symptoms may improve or cease to progress, but they are sometimes the forerunner of gangrene of the extremities. They may end in a condition resembling Raymond's disease, persistent acroparesthesias, or erythromelalgia.

I have examined over fifty hospital patients with a view to determine the frequency of the presence of this foot pulse. I could always find the posterior tibial, but the dorsalis pedis was sometimes absent, or, at least, beyond my power of detection. This is about the experience of Goldflam. Very little has been written about this subject by American physicians, and hence it seemed worth while to report my case, which is not of the classical type, but which certainly belongs, pathologically, in the group of motor and sensory troubles of the extremities due to obliterating arteritis and vasomotor spasm. In my case, I could exclude embolism, but I cannot say that there was not thrombosis. This, however, is in accord with other reported cases.

Summary.—There is a group of symptoms characterized by intermittent or temporary attacks of paralysis, usually of one leg, accompanied with pain, paresthesia, stiffness, and vasomotor disturbances, and absence of pulsation of one or both foot arteries.

It is chronic in course and may lead to gangrene, or symptoms resembling erythromelalgia or Raymond's disease. It affects oftenest one leg, but may attack both, and may affect the arm. It occurs in middle-aged people of neurotic temperament, is due to, or associated with, exposure, alcoholism, gout, diabetes, excessive use of tobacco, and syphilis.

It is due to arterial sclerosis, causing obliteration of the smaller arteries, also to disease such as aneurysm of the large trunks.

The trouble has been called painful paralysis, intermittent claudication, intermittent limping, and, perhaps most appropriately, intermittent muscular paralysis, due to arterial sclerosis. The diagnostic points are the absence of the foot pulse, together with the symptoms above enumerated.

UNILATERAL RIGHT-SIDED VENOUS THROMBOSIS, ASSOCIATED WITH CARDIAC DISEASE; AUTOPSY.*

By JOHN WINTERS BRANNAN, M.D,
NEW YORK.

The case is that of a woman, forty years of age, admitted to Bellevue Hospital, November 1, 1901. The family history was negative. The patient herself had been a steady and heavy drinker of beer and whiskey. There was no venereal history. Five years ago she had suffered from acute articular rheumatism and was confined to her bed five months. Since then she has had many attacks, accompanied with cough, dyspnœa and swelling of extremities. During the past two weeks she had grown steadily worse. Ten days ago the right arm and side began to swell, and the patient became delirious. On admission to the hospital the temperature was 100.2°, the pulse 96, the respirations 36. The patient looked very sick and lay in a drowsy state, answering some question intelligently when roused, but soon relapsing into unconsciousness. There was marked dyspnœa, and the lips, ear-lobes, and nose were very cyanotic. There was general œdema of the whole body. The right arm and shoulder, and right side of the neck, and the right side of the body, front and back, as far down as the umbilicus, were greatly swollen and œdematous. The swelling of the right breast was so great

---

*A few other cases have been reported in the last three years, notably one by Grassmann (*Deutsches Arch. f. klin. Med.*, Vol. LXVI, 1899, p. 500), who proposes to call the affection "Intermittent muscular paralysis, due to arterial sclerosis."

*Read at meeting of Practitioners' Society, January 3, 1902.

that it closely simulated a tumor. Examination of the chest showed the presence of considerable fluid in the right pleural cavity. The heart was enlarged, and at the apex was heard a soft, blowing, systolic murmur, transmitted into the axilla. No abnormal sounds were heard over the aortic, pulmonary, or tricuspid valves, nor was there any thrill or pulsation observed anywhere in the chest. Examination of the abdominal organs gave negative results. The inguinal glands were slightly enlarged, otherwise no glandular enlargement was detected anywhere, save for a small hard firm mass felt high up in the right axilla. No distinct glands, however, were made out. The urine was scanty in amount and contained a marked trace of albumin and a few granular casts. Examination of the blood gave hæmoglobin 72 per cent., red cells 4,352,000 to the cubic millimeter, leucocytes 13,200, increased one week later to 18,000.

On the day following admission, the right side of the chest was aspirated and about three pints of clear straw-colored serum obtained. During the next few days the œdema of the lower extremities diminished, but the general condition of the patient grew worse. There was slight fever, the temperature ranging from 99° to 100.6°. The physical signs in the chest remained the same and the œdema of the right upper extremity persisted. It was evident that there was obstruction of the venous circulation of the right side, but there was no clue as to its cause. I was myself inclined to attribute it to pressure from an enlarged mediastinal gland. Others thought a new growth more probable. Of aneurysm there was no sign. On November 9 the patient died.

The following is the report of the autopsy, made by Dr. E. L. Dow: Body fairly well nourished. Skin very white. Moderate œdema of all of the subcutaneous tissues with considerable straw-colored fluid in all of the serous cavities and with a disproportionate, excessive œdema of the tissues of the right arm, axilla, and forearm.

Dissection down to the large blood vessels in the right axilla showed the right subclavian and the right axillary veins and their small tributaries to be the seat of a firm, white and red thrombus, and the right brachial vein to be filled with a firm dark clot. There was no thrombosis of the jugular veins. The corresponding arteries were apparently normal. No gross evidence of local traumatism or inflammation was present. The thrombus ended abruptly at the beginning of the right innominate in a rounded end. The superior vena cava was free from any thrombus, but the right auricle contained a firm pink thrombus, especially marked in the appendix.

The tricuspid, aortic, and mitral valves were the seat of an acute endocarditis, showing many small red bead vegetations on their edges. The mitral valve was also somewhat thickened and contracted by old fibrous tissue growth. The heart muscle was pale, firm, and somewhat hypertrophied. All of the cavities were much dilated, especially that of the left auricle.

The aorta, coronary, and other arteries showed nothing of importance.

The lungs showed moderate brown induration with œdema, and one recent hemorrhagic infarct in the middle lobe of the right lung. The bronchial lymph nodes were somewhat enlarged and deeply pigmented, but apparently had no relation with the thrombosed veins. The right pleural cavity contained about three pints of clear serum.

The liver and spleen showed only chronic passive congestion.

The kidneys presented an extreme degree of a secondarily contracted white kidney.

The pancreas, adrenals, and bladder showed nothing of interest.

The cavity of the uterus was filled with a small amount of bloody mucus.

The stomach and intestines gave evidence of a moderate chronic mucous inflammation.

The brain could not be examined, as no permission was obtained to open the skull.

There was no evidence of otitis, mastoiditis, or any inflammation in the nasopharynx.

Microscopical examination of the thrombosed veins gave no evidence of phlebitis, and showed the thrombus to be non-organized.

Welch* has so recently and so thoroughly discussed the subject of venous thrombosis in cardiac disease that I shall content myself with simply recording this additional case. The situation of the thrombus is of interest, being on the right side alone, whereas in twenty-two of the twenty-four cases collected by Welch, the thrombosis affected the veins of the left side. Perhaps pressure from the large accumulation of fluid in the right pleural cavity may have been a factor in the unusual localization of the thrombus. It is unfortunate that no bacteriological examination was made in this case, as Welch believes that bacteria are in all probability the immediately exciting cause of the thrombosis, apart from the question of localization.

THE MANAGEMENT OF CRITICAL CASES OF RUPTURED EXTRA-UTERINE PREGNANCY, WITH THE REPORT OF A CASE OF COMBINED INTRA- AND EXTRA-UTERINE PREGNANCY.†

By J. W. ELLIOT, M.D.
BOSTON
SURGEON TO MASSACHUSETTS GENERAL HOSPITAL

THE following observations are based on an experience of twenty cases of my own of extra-uterine pregnancy, in all of which recovery took place after operation, and of cases seen in private consultations, and with my colleagues at the hospital.

As such patients are not afflicted with a disease or an infection in the first instance, but are suffering only from an accidental rupture of a blood vessel, they present the most favorable opportunities for surgical successes. At the present time we have little doubt about our ability to stop hemorrhages, and our aseptic precautions should be perfect. The only seemingly insurmountable difficulty has been that we are frequently called to operate on patients who are exsanguinated and pulseless. Such patients almost invariably die during the operation, or soon after. The proper management of this difficulty is, therefore, of the utmost importance, for if such cases can be successfully operated on, the mortality of ruptured extra-uterine pregnancy should be very low indeed.

In one of my early cases (February 11, 1893) the patient was suddenly taken with weakness and vomiting, and a severe pain in her left side. The pulse became rapid, and she was soon in a critical condition. When she arrived at the hospital the next day she was very pale, with sunken eyes, and a bad expression; abdomen swollen and tympanitic; pulse very poor. I felt certain that she could not live through an operation, and waited to try the effect of twenty-four hours' treatment with stimulants. On the following day the pulse and general condition had so far improved that I was willing to operate, and did so with a good result. I was so much impressed by the rapid improvement of this patient that I have never risked an operation in an extra-uterine pregnancy until my patient had gained a fairly good pulse, and I am astonished to find that none of them have died while waiting for the rally. My experience has been so favorable that I now confidently expect them to rally, and I am sure I have had my share of desperate cases. Let me quote one or two:

---

* "Transactions of the Association of American Physicians," Vol. XV., 1900, p. 441.

† Read before the Obstetrical Society of Boston, December 17, 1901.

On March 9, 1900, Mrs. E. G. entered my wards at the hospital with a typical history of rupture of an extra-uterine pregnancy. "She was very pale and blanched, presenting every sign of hemorrhage. Pulse rapid and almost imperceptible; respiration feeble; extremities cold. She was manifestly unfit for operation." Dr. Mumford saw her and confirmed this opinion. She was stimulated during the night with brandy and coffee, and with hot salt solution per rectum and small doses of morphia. In twenty-four hours her condition had improved very much; her pulse had come down somewhat, but was still very weak. I therefore waited another twenty-four hours, and her condition gradually and steadily improved, so that in forty-eight hours she had a still less shaky pulse, and began to look better. I then operated, finishing with a pulse weak and rapid, but she soon rallied again and recovered.

Another case was seen with Drs. Sabine and Houghton in Brookline, on April 28, 1900. Dr. Houghton had been called to the patient because she had collapsed with a sudden pain and fallen on the bathroom floor. He found her ashen in color, and with absolutely no radial pulse. When I saw her she was ghastly white, unable to speak, and almost pulseless, with cold nose and extremities. The abdomen was moderately swollen and tympanitic. Although her condition seemed hopeless, I gave a hopeful prognosis, saying that in my experience such patients usually rallied enough to make a favorable operation possible. She was treated with stimulants and salt solution under her breasts and small doses of morphia. In twenty-four hours she had notably improved, and in fifty-four hours she looked better, and had a pulse between 130 and 140. Fearing there might still be oozing from the ruptured tube, I took this opportunity to do a rapid operation, and finished with the patient in a critical condition. She was very feeble for two days, but gradually improved and made a good recovery.

On the other side of the question, you are doubtless familiar with the fatal results which attend these operations on patients in a collapsed condition. On looking up the records of the Massachusetts General Hospital for the last five years, I find that seventy-five cases of extra-uterine pregnancy have been operated on, with three deaths, a mortality of 4 per cent., which, I think, is a good record, considering the fact that unfavorable cases are frequently sent there as a last resort. On looking over the records of the three cases that died, I find that they were all operated on soon after entrance, and all were in a more or less collapsed state.

CASE I.—Patient very weak and of a yellowish color; entered the Massachusetts General Hospital August 27, 1897; temperature 101.4°. There was great prostration, with a very weak pulse. An infusion of two pints of salt solution was given in the arm. Brandy and strychniæ were given during the night. Operation was performed the next morning after the patient's entrance. The abdomen was washed out and left full of salt solution, with a wick in the pelvis. The patient was infused with salt solution during the operation. She died the next day—sepsis?

CASE II.—The patient entered hospital October 11, 1899. Temperature 102°; pulse 132. Patient cyanotic, with cold extremities. Operation immediately after entrance. Abdomen washed out; wicks in pelvis. Pulse 180 during the operation. Died next morning.

CASE III.—The patient entered September 27, 1900; temperature 100°; pulse 120; in very poor condition; immediate operation under little more than primary etherization; abdomen washed out; patient infused and given strychnia during operation; died soon after operation.

In the last report of one of the large American hospitals I find in the table of surgical operations cases of ectopic gestation with six deaths. The deaths are accounted for as follows:

1. Exhaustion, four days.
2. Exhaustion, hemorrhage, five days.
3. Shock, hemorrhage, forty-eight hours.
4. Shock, hemorrhage, twenty-four hours.
5. Shock, six hours.
6. Hemorrhage, three days.

Waiting and stimulating could scarcely have failed to have improved these results.

One rarely hears of a person dying of extra-uterine pregnancy without the assistance of a surgeon, but we constantly hear of persons who have not rallied from the operation.

Beside finding by experience that it is a better practice to wait for a rally in these critical cases, I think I see other reasons for waiting. After reading the records of twenty or thirty of these cases, it becomes apparent that they run a chronic or a subacute course after the first collapse. The histories usually read something as follows: The patient suffered a sudden severe pain in the left side, and fell down in a faint; pallor, feeble pulse, and a critical condition for several days; up and about in a week; after ten days or two weeks another attack like the first, perhaps more or less alarming. This sort of history runs on from ten days to three or four months. The hemorrhage in these cases then has a marked tendency to stop and to recur. Perhaps it stops on account of a weakened heart stroke. We usually find on the top of the pelvis a mass of intestines matted together with firm adhesions, which must offer considerable resistance to a rapid pouring out of blood. Moreover, this blood is not wholly lost to the patient, but is more or less reabsorbed by the peritoneum.

When a patient begins to rally from the severe prostration of one of these hemorrhages, it is no easy matter to decide when the operation should be done. If we wait too long, the bleeding may begin again, or we may conclude that there is a steady ooze which does not stop. It requires the best kind of surgical judgment to choose the most favorable moment for operation. In view of the above argument, I feel sure it is always safer to wait than to operate in a doubtful case.

The operation should be done quickly and accurately, without excessive handling. I usually scoop out enough of the clotted blood to enable me to find the uterus. I then quickly pass a ligature around the uterine end of the affected tube; this sometimes stops active bleeding, and is a useful handle to pull the tube into view. I next pass a ligature around the other end of the tube and remove the tube from between the ligatures. I never wash out the abdominal cavity or try to clean out the clots, because the blood in the abdomen is just what the patient needs, and the manipulation required to remove it takes time and produces shock. Washing out also requires time and more apparatus, and, therefore, adds to the danger of errors in aseptic technique. I almost always close the abdomen without drainage.

A Case of Combined Intra- and Extra-Uterine Preg-

nancy.—The patient, Mrs. A., aged thirty-five years, and thirteen years married, was sent to me in November, 1890, by Dr. Croston of Haverhill. She had had a miscarriage, and complained of a persistent pain in her left side. I found a small tumor to the right of the uterus. On December 27, 1890, I operated and found a cyst of the broad ligament on the right side, as well as several small cysts of both ovaries. I removed the right ovary and tube, but excised the cysts from the left ovary, stitching the ovarian wound together so as to leave about half the ovary in good condition. After the operation the pain in her side continued more or less severe until 1895, when the uterus was curetted. This was soon followed by pregnancy, and a child was born in October, 1896. She was then very well until her present illness.

On December 17, 1900, she had her last regular menstruation; one month later there was only a slight staining. Two weeks later she had another slight show and an attack of severe abdominal pain, which caused her to turn white. A physician was called, who injected morphia, saying that she was having a miscarriage. She remained in bed five days. Two days later, January 27, Dr. Maurice Clarke was called, and found her flowing and in severe pain. She got up the next day, and was fairly well during the next week, when Dr. Clarke sent her to me, thinking she might have an extra-uterine pregnancy. She came to my office on February 4, when I found the uterus somewhat enlarged and softened. I also noticed that the left ovary was considerably enlarged, but she said that I had told her that the ovary was enlarged several years before. I wrote to Dr. Clarke that I thought she was pregnant, but could not be certain whether it was an intra- or an extra-uterine pregnancy, and advised careful watching. On February 9 she had severe pain and flowing, and on February 11 she passed a piece of membrane as large as two thumbs, which was examined by Dr. Benson of Haverhill, and found to contain chorionic villi; later a small fœtus was found in this membrane. Two days later Dr. Clarke curetted the uterus on account of a slight odor of the discharge with some rise in temperature. She seemed to do well for several days, but during the next two weeks she suffered from gas and abdominal pain. At last she sat up in a chair, and this brought on a very severe abdominal pain, which required morphia. The pain and gas continued in spite of every effort for relief. I was called to see her on February 25, and found her so very white and sallow that I immediately suspected internal hemorrhage. The pulse was somewhat accelerated, and the evening temperature had been running up to 101°. The abdomen was swollen and tympanitic, and a large mass could plainly be felt extending up from the pelvis half way to the umbilicus. It seemed to be a typical case of ruptured extra-uterine pregnancy, except for the fact that she had already had a miscarriage. We also had to consider the possibility of the pelvic tumor being an abscess due to infection from the miscarriage, but her pallor and a moderate mobility of the mass were signs in favor of extra-uterine pregnancy ruptured. The question was a difficult one, and I operated without being perfectly sure which it might be.

Operation, February 26.—I found the pelvic tumor consisted of a large mass of dark blood clots, which I partially turned out; the left Fallopian tube was much enlarged, ruptured and bleeding; the uterine end was normal in size and appearance; it was cut away between two ligatures, and the bleeding entirely ceased; the clots were partially wiped out, and the abdomen closed tightly without washing or drainage, the patient made a rapid and perfect recovery, sitting up on the fifteenth day. Dr. Whitney's report on the embryo passed at the miscarriage and of the tube removed at the operation:

"The specimen of Mrs. A., Haverhill, February 27, 1901, consisted of about 8 cms. of the Fallopian tube, which was dilated. In one part was a more or less homogeneous, hemorrhagic mass closely infiltrating into the wall and measuring about 3 cms. The surface, which projected into the tube, was very much roughened and shaggy. The preparation made from this showed branching filamentous threads, with club extremities, characteristic of the villi of chorion in the early months of pregnancy. Careful examination failed to reveal the presence of any other structure of the embryo.

"The embryo, which was received previous to this specimen, measured about 3 cms., was considerably macerated, and ossification of the ribs and skull was well marked. It was estimated to be somewhere in the neighborhood of two and one-half to three months. The exact stage of the chorion villi in the tubal specimen could not be absolutely determined beyond that it was very nearly the second month. If other chorion villi were found in connection with this embryo, it shows that there must have been a double pregnancy, one intra- and the other extra-uterine, for there does not seem to be any marked loss at the place where the villi are adherent to the wall of the tube."

Points of Minor Interest.—A constant pain in the left side, lasting for several years, dating from a miscarriage, was due to a chronic endometritis, and was cured by curetting. A sterility of seven years was cured by the same curetting. A conservative operation on a small cyst of the left ovary made pregnancy possible. An extra-uterine pregnancy followed an old endometritis and a varied gynecological experience. Pallor and moderate mobility of a rapidly growing pelvic tumor led to the hypothesis of another pregnancy (extra-uterine) as against a pelvic abscess due to infection from a recent miscarriage.

I have found accounts of seventy published cases of combined intra- and extra-uterine pregnancy. One interesting case is recently reported by Mrs. Boyd, M.D. (*British Medical Journal*, October 5, 1901.) In this case the doctor found the uterus enlarged and softened, and Douglas fossa filled with a mass. When first seen the uterus was the size of an ordinary extra-uterine pregnancy, but on further observation it was found that the uterus was increasing in size, while the mass decreased. Abdominal section was done, and the right tube, size of an orange, was removed and found to contain chorion villi. The patient was later delivered of a healthy child.

Unusually High Death Rate. Although fewer cases of typhoid fever and of smallpox are reported to the Philadelphia Bureau of Health for the week ended February 15, the total number of deaths was unusually large—namely, 602, as compared with 581 for the preceding week and 522 for the corresponding week of the previous year, and with 503 for the corresponding week of two years earlier. A round hundred of deaths were due to pneumonia, while sixty-four resulted from pulmonary tuberculosis; forty-seven were due to nephritis, thirty-eight to diseases of the heart, twenty-eight due to typhoid fever and also to gastritis and enteritis, twenty-three to apoplexy (not including ten due to paralysis), nineteen to smallpox and also to old age, sixteen to diphtheria. Twenty-one deaths are attributed to "inflammation of the brain." The number of cases of typhoid fever for the week was 157, of smallpox 74, of diphtheria 671, of scarlet fever 62.

A PRELIMINARY NOTE ON THE PREVENTION OF NAUSEA AND VOMITING FOLLOWING ETHER ANÆSTHESIA.*

By RALPH J. HESS, B.S., M.D.,
BELLEVUE HOSPITAL, NEW YORK.

SINCE the discovery of the use of ether as an anæsthetic by Morton, in 1846, there has been a continued attempt to rid anæsthesia of one of its most disagreeable, if not dangerous, features, viz., nausea and vomiting following anæsthesia. No part of the ordeal of undergoing a surgical operation is more distasteful to the patient than are the retching, nausea, and thirst which are suffered in post-anæsthesia cases. The danger of vomiting is so well recognized to-day that every surgeon insists that the patient shall have no food for six to eight hours previous to the operation. Anæsthesia statistics show an appreciable death-rate from inhalation pneumonia, which is the result of inspiring mucus and vomitus during vomiting.

The literature on this subject shows that numerous investigators have endeavored to solve the cause and apply the proper remedy. Hewett believed vomiting to be a characteristic effect of the drug, and advised the use of pure ether. Webster and Blumfield assigned the cause to the quantity of mucus swallowed during the commencement of anæsthesia. Others have thought vomiting to be due to the action of the ether circulating in the blood on the vomiting center of the medulla. Golden thinks it more frequently the result of improper preparation of patients and improper methods of administering the anæsthetic, rather than to the result of the drug itself.

A long list of remedies has been proposed as preventatives and cures for post-anæsthesia vomiting. Kappler recommends the application of an ice bag over the stomach. Hewett noted that a draught of hot water often relieved vomiting. Hare advises the use of atropine, in doses of 1-1,200 of a grain, given just previous to the anæsthetic. Snow used brandy and water in small doses, given after the operation. Arongon used a cloth wet with vinegar applied to the nose after anæsthesia. Camphor monobromate, sodium bicarbonate, and cerium oxalate are drugs in common use, which are given with the hope of lessening vomiting after anæsthesia. Hirschman of Detroit has recently published a paper in which he urges the use of chloretone in doses of ten to twenty grains, given one hour previous to the anæsthetic. Several surgeons use the method of spraying the nose and pharynx with a cocaine solution before anæsthesia.

When I first started to work on this subject, I believed that gastric irritability was due to swallowed mucus and ether, so I endeavored to stop vomiting by washing out the stomach after etherization. This practice lessened, but did not stop vomiting. I found on washing out the stomach after anæsthesia that the stomach contents contained traces of ether. This led me to think that it might be possible that ether is excreted from the blood into the stomach and, acting there as an irritant, causes all of the phenomena of gastric irritation and subsequent acute gastritis.

The experimental proof that ether is excreted by the mucous membrane of the stomach, I have endeavored to obtain in the following way: I selected cases which did not get up bronchial irritation with excess of mucus, and withdrew the stomach contents of these cases with a stomach tube, shortly after the anæsthetic was stopped. Ether was found present in sufficient quantities in these cases to give a distinct odor to the specimen, but time did not permit me to use the usual chemical methods for determining the actual amount of ether present.

In a later paper on this subject, I shall publish the results of some experiments on animals, by which I hope to demonstrate that ether is excreted by the cells of the mucous membrane of the stomach, and that it produces there, pathologically, an acute gastritis. Such experimental evidence, coupled with the results of the microscopic examination of the kidneys of animals which have inhaled large quantities of ether vapor, will show, I predict, that ether is capable of producing definite and well-marked lesions during the excretion.

The clinical evidence in support of this theory can be seen in the everyday routine of ether cases. The use of small quantities of ether in short operations causes little gastric disturbance, and the patient feels well again in a couple of hours. The use of the closed inhalers—as those devised by Bennett, Clary, and Goldan—has shown that by lessening the quantity of ether used patients do better in every way.

Acting on this theory that ether is excreted into the stomach, I have endeavored to find a treatment for other cases which would do three things: Accelerate the excretion of ether, prevent its irritant action in the stomach, and reduce the quantity of ether used to a minimum.

The excretion of ether, as well as the excretion of any other poison, is facilitated by saturation of the patient with water. Such a saturation obtained by giving water freely up to the very minute anæsthesia is begun, gives the kidneys, lungs, stomach, mucous membranes, and skin a chance to excrete ether rapidly. The treatment of ether cases in vogue to-day does exactly the opposite, viz., as much fluid is extracted from the patient by means of cathartics, salines, and enemas, before anæsthesia, as possible; added to this is the fact that many surgeons forbid the patient to take fluids for several hours previous to the operation. Such treatment sends the patient to the operating table with a dry skin, parched lips, small pulse, excreting urine of a high specific gravity (1,025-1,040), in fact, in no condition to excrete a large amount of an irritant poison. A century ago Claude Bernard proved that ether acted on each tissue of the body, and we believe this to-day, but still do not provide for the excretion of such an irritant.

Preventing the irritant effect of ether on the stomach requires simply the dilution of the ether as it is excreted. A glass or so of water drunk at the commencement of anæsthesia serves to hold in solution considerable ether (ether being soluble in water in the proportion of 1-10).

The limiting of the amount of ether used in all cases is, I believe, a most important factor. The use of closed inhalers has done much to aid this. By means of an inhaler, such as has been devised by Dr. Bennett, with the inducting of anæsthesia by means of nitrous oxide, the amount of ether actually needed for any surgical operation can be greatly reduced by proper care and skill. Comparing my ether statistics when I used the ordinary Allis inhaler with the results obtained with the Bennett inhaler, I find I use one ounce now where I used eight to ten ounces then. A better type of anæsthesia is obtained, and the safety to the patient is greatly enhanced.

The question of preventing an excess of secretion of mucus in the larynx and bronchi is important in this connection. Such mucus, if excessive, is swallowed, and adds to the gastric irritability. The cause is too strong ether vapor. Ether vapor, concentrated enough to cause spasm of the glottis, gagging, and resistance of the patient, is strong enough to cause irritation of the respiratory mucous membrane with excess of mucus. Spencer proved by experiments on that vapor containing 3.5 per cent. ether would anæsthetize animals for several hours without affecting the phase of respiration. The vapor in the ordinary inhaler is much more concentrated. A comparison between the concentration necessary to carry on anæsthesia and the strength in every inhaler shows that a too highly concentrated ether vapor is ordinarily used. This is the cause of excess of mucus.

---

*Dr. Hess' death occurred before this MS. was sent for publication.

I report the following cases from the gynecological service of Dr. W. M. Polk at Bellevue Hospital, and in reporting them I wish to express my indebtedness to Dr. Polk for so kindly extending to me the opportunities for investigating this subject. These cases received no further treatment than ℥ vj-℥ x water just before beginning the anæsthetic and plenty of water after, and are consecutive cases in that they are the only cases which have received this treatment.

Case I.—K. D., aged twenty, curettage, January 14, 1901. Six ounces of water were given immediately before beginning the anæsthetic. Anæsthesia with NO followed by ether. Began 3.15, under anæsthetic by 3.18, operation began 3.48, ended 4 o'clock; quantity ℥ jss. Patient recovered 4.15; patient urged to drink water by nurse as soon as conscious. No nausea or vomiting.

Case II.—M. S., aged eighteen, perineorrhaphy, January 15, 1901. Six ounces of water were given before the anæsthetic. Anæsthesia with NO and ether. Began 2.10, under 2.12, operation began 2.25, ended 2.45; ℥ j. Patient recovered 2.55, and was given ℥ x water. Result, no nausea or vomiting.

Case III.—M. F., aged twenty, post-partum curettage, January 18, 1901. Six ounces water given immediately before beginning the anæsthetic. Anæsthesia with NO followed by ether. Began 2.10, under anæsthetic 2.12, operation began 2.30, ended 2.45, recovered 2.58, ℥ ij water was given as soon as patient was conscious. Result, no vomiting.

Case IV.—L. M., aged twenty-five; post-partum curettage, January 18, 1901. Six ounces water given before the anæsthetic. Anæsthesia by NO and ether. Began 3.05, under 3.11; operation began 3.20, ended 3.50; recovered 4.10; ℥ iss; water given freely after operation. Result, no vomiting.

Case V.—N. J. B. H., aged twenty-three, curettage and packing, February 1, 1901. Preparation of patient same as in Case I. Anæsthesia with NO followed by ether. Began 1.59, under 2.03; operation began 2.30, ended 2.50; patient recovered consciousness 4.05. Amount of water given freely after operation; ether, ℥ ji. This case had, entirely against orders, taken solid food previous to the operation. Patient vomited once before consciousness was regained.

Case VI.—S., aged twenty-one; double salpingo-oophorectomy, February 4, 1901. Same patient given ℥ vj water just before anæsthetizing. Anæsthesia with NO followed by ether. Began 2, under 2.01, operation began 2.35, ended 5.00; ℥ jv.; patient recovered 6 P.M. Saline infusion under breasts 7.30 c.c. given at 5 o'clock. Patient did not vomit.

Case VII.—R. H., Bellevue Hospital, aged twenty, February 8, 1901; case of post-partum curettage. In preparation for operation patient was given 2 c.c. pills at night followed by ℥ ss of Rochelle salts at 5 o'clock the following morning. No breakfast allowed other than a cup of coffee. Patient was given ℥ viij of water before beginning the anæsthetic. Anæsthesia with NO followed by ether using the Bennett inhaler. Began 2, under 2.02; operation began 2.30, ended 2.45. Patient recovered consciousness 2.45. No vomiting.

Conclusion.—1. Post-anæsthesia vomiting is a source of danger and great discomfort to patient and is preventable.

2. It is due to excretion of ether into stomach with resulting acute gastritis.

3. Drugs are of no avail in prevention or treatment of post-anæsthetic vomiting.

4. The present technique of preparation of patients for etherization is faulty, in that fluids are usually entirely prohibited or limited, whereas they should be pushed to aid in excretion of ether.

5. The dose of ether should be as small as possible and the strength of ether vapor should not cause bronchial irritation with excess of mucus.

6. The combined use of NO and ether gives the best results.

7. In anticipation of gastric irritation, give one to two glasses of water just before beginning anæsthetic.

Diagnosis of Aortic Aneurysm.—A. R. Edwards mentions, among the various differential points, the following: Differentiation from solid tumors rests upon their propagated non-expansive pulsation, their more rapid development, lues, tonus and cachexia. In aneurysm, the lymph glands may be enlarged either from lymph stasis or from extension to them of inflammation about the aneurysm. Their enlargement is much more frequent, however, in mediastinal tumor, and continued increase argues directly for neoplasm. Pain, recurrent paralysis, dysphagia, are common to all tumors, vascular or neoplastic; venous ectasia is more common in tumor. A few rare instances of coincidence of tumor and aneurysm are observed. The pulsation in carcinoma is sometimes associated with a "back stroke" in the diastole, but this is feeble if present. The bruit in tumor is usually systolic, while murmurs are not rarely absent in aneurysm. Tugging is present in both. The time element is important, aneurysm running a much more protracted course. Exploratory puncture and diagnosis *ex juvantibus* with iodide are also differentially important. Finally, differentiation from other causes for pulsation, a throbbing, aortic regurgitation, beating in aortitis, pulsation in pneumonia (Graves), in tumor of the lung or pleura, in serous or purulent pleurisy, is usually made when all symptoms and signs are carefully weighed.—*Illinois Medical Journal.*

The Action of Quinine on the Malarial Parasite.—Achille Capogrossi concludes, from experimentation, that the presence of quinine in solutions added to preparations of malarial blood, is not in direct relation to the expulsion of the parasites from the red corpuscles, inasmuch as this may be produced by solutions of various alkaloids, and by other fluids. Neither is this expulsion obtained with constancy under identical conditions, but appears to depend on various other factors, such as the discoloration and swelling of the corpuscle. If quinine be added to malarial blood under conditions which prevent this swelling and discoloration, the expulsion will not take place. The curative influence of quinine in malaria can, therefore, not be due to its expelling the parasite from the cell.—*Il Policlinico.*

A Case of Acute Gastric Catarrh Simulating Ulcer of the Stomach.—G. Jacontini was called to see a patient suffering from intense pain in the epigastric region, with incoercible vomiting, which had been a symptom for some time, and which was frequently bloody, and from a general condition of depression. Everything pointed to ulcer of the pylorus. The course of the disease, however, showed that this was not the cause of the trouble. The author does not describe the treatment adopted, but the pain and vomiting disappeared, and in about twelve days the patient was cured. The conclusion is reached that it was a case of unusually intense and acute gastric catarrh.—*Giornale Internazionale delle Scienze Mediche.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, February 22, 1902.

WHAT CONSTITUTES SUCCESSFUL VACCINATION.

BETWEEN efficient vaccination and successful vaccination there is a great difference. The operation may be performed efficiently and yet not be successful. In order to confer immunity to smallpox upon a person several contributory circumstances must be taken into account—the condition of the lymph, the thoroughness of the vaccination, and the state of the individual's health at the time.

Dr. Durgin, Chairman of the Boston Board of Health, writing in the *Boston Medical and Surgical Journal*, January 30, says: "To secure full vaccination, I believe that a child should not only be vaccinated when very young, but that the physician should feel called upon to exhaust all susceptibility to smallpox by repeating the operation until it will no longer take effect." The same writer, referring to vaccine, says: "The difference between humanized and bovine lymph in the Republic of Mexico is shown by the fact that for ninety-seven years in that country they have used almost nothing but humanized lymph. They never revaccinate, neither do they have smallpox among the vaccinated." The success of these methods in Mexico so greatly impressed Dr. Durgin that at the last meeting of the American Public Health Association he prevailed upon that body to appoint a committee to investigate and report upon the respective immunizing power of human and bovine lymph.

The Boston physician, with regard to the technique of the operation, says: "A scarification one-eighth to one-quarter of an inch in diameter is ample. The use of a shield on the whole is a nuisance, but care in rubbing on and drying in the lymph is important. The physician should always see the patient at the end of a week or ten days, and tell him whether or not there is a typical vesicle, and if it is not, should repeat the operation."

Dr. Sidney Coupland, at a recent discussion of the Royal Medical and Chirurgical Society, in London, on vaccination, said, concerning what might be regarded as efficient vaccination, that since the purified lymph might give rise to such a small amount of scarring, the size and area of the scars could no longer be considered as evidence of effective vaccination, and reliance would have to be placed rather on the number of scars than on either their depth or area. It was a well-recognized fact that those persons with more scars were better protected than those with fewer scars. With regard to the protective value of a previous attack of smallpox, he said that out of 250 people who had been stricken in childhood, ten contracted a second attack when exposed to infection. With regard to the protective value of vaccination, he said that about one in four persons who had been vaccinated in infancy contracted smallpox if exposed to infection in later life.

Revaccination conferred absolute immunity, and even in a patient who had had smallpox the immunity could be prolonged by vaccination. In children under ten years of age who had been vaccinated in infancy, the liability to contract smallpox when exposed to infection was one in twelve, while in those who were unvaccinated the liability was two in three.

Dr. Coupland did not consider all even recently vaccinated persons were absolutely immune, owing to their vaccination with various strains of lymph, some of which might have become inert.

Dr. Copeman considered that the same amount of vaccination was necessary in the child as in the adult, and, as a rule, the vesiculation was less severe in relation to the amount of vaccine used in the child than in the adult. With regard to inert lymph, he said that when it was suspected that a vaccination had failed because of inert lymph the patient should not at once be revaccinated, but should wait a month for a certain amount of local immunity sometimes produced even by an apparently inert lymph. It was generally assumed that the glycerinated lymph was less patent than the older form of lymph. This he did not think was the case, for in the preparation of the calf lymph the epithelium in which the vaccine organisms were supposed to be was scraped off, whereas in the lymph obtained from the vesicles only the fluid was taken.

The definition of a successful vaccination, presumably, is that by means of the method conducted efficiently, an individual is rendered immune to smallpox for a period or throughout his life.

There is, however, a certain amount of difficulty in deciding when a person is thus free from the infection of the disease, and the advice of Dr. Durgin "that the physician should feel called upon to exhaust all susceptibility to smallpox by repeating vaccination until it will no longer take effect," would seem to be based on sound premises.

As to whether humanized lymph possesses the remarkable immunizing qualities attributed to it by Dr. Liccada of Mexico is a point which certainly calls for investigation.

In order to perform vaccination thoroughly under present conditions, pure and fresh lymph is the first essential; strict aseptic precautions must also be used, and a sufficient area must be operated upon for the purpose of vesicular absorption.

Revaccination must also be practiced whenever deemed necessary. By following such methods vaccination will attain its greatest possible success.

THE TREATMENT OF TUBERCULOUS PERITONITIS.

MANY collections of statistics and many reported cases of tubercular peritonitis have seemed to confirm the dictum that the operative form of treatment holds out the best prospect of curing or ameliorating this form of tubercular infection. During the last few years, however, the disease has been studied closely, and observers have come to recognize that there are several more or less well-marked varieties which pursue different clinical courses, and are amenable to treatment in different degrees. The clinical differ-cures, as might be expected, depend upon differences in the character of the pathological lesion.

In *Annals of Surgery*, December, 1901, Fenger of Chicago publishes a paper on the disease in question, and while offering many personal experiences and ideas, he also quotes from a paper by Borchgrevink, who seems to have analyzed the subject in a very satisfactory manner, and to have made some valuable suggestions. Both these writers agree with most others in recognizing three varieties of the disease: a suppurative form, a serous exudative form, and a form characterized by the formation of adhesions. It is easy to see that the possibilities and outcome after operation, in cases of these different classes, would be influenced by the extent and character of the pathological changes, and some of the discrepancies in clinical reports undoubtedly depend upon an imperfect recognition of these differences, which must often have been manifest at the time of operation, though their significance may frequently have been misunderstood. The form of the disease characterized by the accumulation of quantities of caseous matter among the coils of intestines, which are more or less adherent, naturally offers much greater surgical difficulty than a case without adhesions, in which the peritoneum is studded with miliary tubercles, and in which there is a collection of clear or turbid serous fluid. The caseous matter, in the first type of case, is very prone to disorganization into a purulent fluid much like that found in tubercular joints. The form of tubercular peritonitis, in which the formation of adhesions is a prominent condition, is, as might be supposed, not favorable for operative treatment, but it is comparatively uncommon.

With these differences in pathology before us, it is easy to understand how operators have had variable experiences in attempting to benefit patients by opening and washing out the abdomen. Those cases without adhesions, and with a collection of serous fluid in the abdominal cavity, have been those in which the best results have naturally been obtained. When there have been adhesions with collections of tubercular purulent matter in various parts of the abdomen, the evacuation of one or two such, immediately in the line of the incision, can obviously have no effect upon those which are remote. The opinions of observers upon the best plan of treatment, when adhesions are extensive, are contradictory and inconclusive. Some believe that, in many cases, benefit is accomplished by incision; but most, and among these Fenger and Borchgrevink, think that no good can be thus accomplished. There is, without question, considerable danger of causing a fecal fistula by operating upon such cases, and this is a serious and unpleasant complication, and the chance that the tubercular process can be thus stopped, is very small. It is a safe general rule to say that, when a patient's general condition is good, and he is free from fever, laparotomy will prove beneficial, unless some unexpected intraabdominal complications are met with. When the tubercular process is a progressive one, as is manifested by fever and other symptoms, the operation will cause a serious drain on the resources of the patient, and much better results can be attained by medical and dietetic treatment. The prospects are not, however, alluring. The writers whose views we are discussing say, in conclusion, that tubercular peritonitis is a condition which the surgeon must hand back to the physician, admitting that his best efforts have been unavailing, to render it reasonably amenable to surgical treatment, except in a few cases belonging to a pretty well defined division of the subject.

The radical operations which have been attempted upon tubercular lesions in the peritoneum have proved uniformly disappointing, and attempts to cure the disease by such means are not justifiable.

THE DESTRUCTION BY THE PANCREAS OF A SUBSTANCE INHIBITING GLYCOLYSIS.

The relation of the pancreas to glycosuria and diabetes has been the subject of many recent researches. Lépine and Boulud, at the meeting of the Société de Médecine of May 7, 1900, announced that they have succeeded in extracting from the urine of patients with diabetes, and from that of patients with pneumonia, a crystalline substance, which, injected under the skin of a guinea pig or introduced into the jugular vein of a dog, produced glycosuria in these animals.

Further researches along the same line, conducted by the authors mentioned above, were reported in a recent number of *Lyon Médical* (January 25, 1902). Lépine and Boulud have perfected the process of extracting the crystalline substance which produces glycosuria, and have tried to find in what way it causes the appearance of sugar in the urine. They added a small quantity of this substance to 100 cc. of the normal defibrinated blood of a dog, and found that, after standing for an hour at the temperature of 38° C., this blood had lost but very little of its reducing power and of its fermentable sugar, while under the same conditions normal blood shows a strongly marked diminution of the reducing power, and an almost complete disappearance of the fermentable sugar. In this manner they established the fact that very small quantities of this substance impede glycolysis in the blood.

They next added a few centigrammes of this crystalline substance, obtained from several litres of urine from pneumonia patients, to a litre of the normal defibrinated blood of a dog. After having convinced themselves that this amount of toxic substance was sufficient to inhibit glycolysis, they passed this blood through a large portion of a dog's pancreas, which they isolated in the living animal for this purpose. Collected from the principal vein, immediately after its passage through the pancreas, this blood was found to have recovered its glycolytic power. The authors conclude that these experiments demonstrate.—(1) That the crystallizable substance extracted by them from the urine of patients with various diseases impedes glycolysis; (2) That this substance is destroyed during its passage through the vessels of a living pancreas; (3) That, therefore, in addition to its other functions, the pancreas exercises an antitoxic faculty, which is of the greatest importance. The pancreas favors glycolysis in the tissues, by destroying the substance which inhibits the decomposition of glucose.

The corollary to this conclusion, although it is not stated by the French authors mentioned, would naturally be that anything that disturbs the functions of the pancreas, be it faulty diet or disease, will affect unfavorably its action of promoting glycolysis in the tissues. It would be of great interest to determine, if possible, the exact chemical nature of the crystalline substance isolated by Lépine and Boulud, and the conditions under which it is produced in the body.

HOME TREATMENT OF TUBERCULOSIS.

Dr. Lawrence F. Flick of Philadelphia has been for long a voluminous writer upon, and an energetic advocate of, the home treatment of pulmonary consumption.

By home treatment he means treatment of the disease at the place where it was contracted, in contradistinction to treatment in a climate selected for its curative qualities.

He further divides home treatment in two divisions, one of which is known as closed treatment and the other as open treatment.

Dr. Flick, in a pamphlet reprinted from the *Journal of Tuberculosis*, gives the result of his experience with regard to these forms of treatment.

By closed treatment is meant such as is obtained in a sanatorium, in which the patient is shut off from the world, and is subjected to strict discipline. By open treatment is meant that at the patient's home, among his relatives and friends, with possibly some occupation and with considerable liberty.

Naturally, Dr. Flick is of the opinion that the closed treatment possesses many and manifold advantages over the open treatment, but taking into consideration the undoubted fact that the latter is the only treatment which is practicable at the present time for the average case, his paper is restricted to an exposition of his views with regard to the care of the consumptive at home.

In the first place, the need of an early diagnosis is emphasized, and the general practitioner is advised to be a little more on the alert in looking for tuberculosis than he has been in the past, and the various physical and other symptoms denoting lung trouble are briefly enumerated.

The food question is dealt with at some length, and, except in cases of poor digestion, Dr. Fleck favors forced feeding, although, perhaps, not to the excessive extent insisted upon in most German sanatoria.

With respect to fresh air, the views expressed are in line with those of the majority of modern authorities on the treatment of tuberculosis.

Absolute rest is recommended if the disease be in an active stage, but moderate exercise if incipient or if activity has been arrested.

Medication, thinks Dr. Flick, is an important factor in the successful treatment of tuberculosis, if the drugs are judiciously and intelligently used.

The iodine compounds used in solution as inunctions are especially praised, and various drugs are advised; to be administered, however, with due regard to the individual's idiosyncrasies and condition. Opiates and antidiaphoretics find no place in the list.

The following table will show the result of Dr. Flick's open treatment:

Cured	18 per cent.
Disease arrested	10 "
Very much improved	26 "
Temporarily improved	19 "
Not improved	27 "

Open treatment of pulmonary tuberculosis must be the one relied upon, until sanatoria are far more plentiful than now. And it is well that a good knowledge of such treatment should be widely diffused by means of intelligently-written articles on the subject.

The fact that climate does not exert the preponderating influence, formerly attributed to it, upon tuberculous patients, is now thoroughly understood. In some cases those rationally treated at home will make a more favorable progress than others who have been despatched to a highly vaunted health resort.

The assertion may be made that the consumptive at the present time stands a better chance of regaining health than ever before, and the outlook for the future is yet more promising.

THE RACE QUESTION IN THE UNITED STATES.

The increase of the colored population of this country provides a fruitful theme for discussion, and is viewed by many able writers through very different spectacles.

Some think that the importation of negroes to America has been in every way a most deplorable circumstance, and that if it were possible to banish the entire community of black people, that the white inhabitants would greatly benefit by such an expulsion. Others hold that the remedy lies in educating the negro, and teaching him to become a useful member of society.

Mr. R. P. Brorup has recently published a pamphlet, in which he treats the subject on somewhat novel lines. He commences by denying that any real benefits are conferred upon the civilized world by teaching savage or pagan nations, methods whereby they are enabled to prolong life, and points out that Holland has, by the brains of her civilization, doubled the number of adherents to Mohammedanism in the island of Java in less than thirty years; while England has achieved nearly as much for Egypt in a like space of time.

This doubling of population of various kinds may be conceived of, says Mr. Brorup, as achievements more splendid in the process than the final results. The ability to do it may be a matter of boasting, but a far-sighted policy would rather shrink from the responsibility, both as a matter of self-preservation, and in view of the possible effect on the world's best interests.

The writer then turns his attention to the situation as regards race in the United States, and delivers himself as follows: "The native Americans have suffered in the struggle with foreigners for numerical supremacy; physically their strength and endurance has proved unequal to the contest. Their superior mental qualities, instead of helping their own race, are at the service of their competitors for the possession of the country; they will invent, plan, and direct, and by their intellectual activity give the latter that chance for growth and expansion of which, with their superior physical endowments, they are able to take full advantage. Thus we have the sociological phenomenon of a people of a country, after being overcome in a struggle for existence on the ground of brute endurance, helping its competitors by its intellectual activity and accumulation of capital to complete the conquest.

From the foregoing quotations it will be gathered that Mr. Brorup does not so much fear the negro population as the constant influx of cheap alien labor from abroad, and thinks that regulation and restriction of immigration in favor of nationalities kindred to our own race, and capable of assimilation, would seem an obvious measure if the interests of our civilization are an object of any concern.

There is no more complex problem, and no one more difficult to solve than this of immigration. It is, however, a sociological rather than a medical question, and yet, in a measure, it bears upon the health of the population of the United States as a whole.

The old stock native-born American is inclined to brain development at the expense of physique, and needs the infusion of fresh blood to produce the *mens sana in corpore sano*.

Nevertheless, it cannot be doubted that a large number of immigrants make undesirable citizens in every way, and should be discriminated against as far as possible.

Scientific Work in America.

Mr. Carl Snyder's article in the January number of the *North American Review*, in which he declared that the United States was far behind Europe in almost every branch of scientific research, has drawn forth many and emphatic disclaimers. Some, however, of the papers written to refute this statement have prejudiced their own case by the vehemence of their arguments, and err quite as much on the side of exaggeration as did the article which caused their protests.

Dr. Simon Newcomb, in the *North American Review*, February, gives a fair and dispassionate presentation of the present conditions of scientific work on this continent, and shows that Mr. Snyder's picture is now not true, whatever it may have been in the past.

Dr. Newcomb points to the munificence with which private individuals have endowed our institutions for learning and research as a proof of the high appreciation with which our people regard the acquirement of knowledge, and urges that this alone is a sufficient answer to the charge brought by Mr. Snyder.

The eminent scientist claims that it is in our failure to estimate the individual scientific investigator that we stand so far behind other enlightened nations, and clinches his argument with several prominent examples drawn from the list of distinguished men of learning and science of Europe and of this country.

Again, the treatment of national scientific organizations of Europe and of America is cited as an evidence that the Government of the United States displays no keen interest in advancing the cause of science or of scientific men.

Dr. Newcomb thinks that the cure for these conditions is to introduce the academic element into the political atmosphere of the capital, and considers that the most effective way to bring this about would seem to lie in the establishment of a great university or other scientific institution, having as little connection with the government as possible, yet not so foreign to it as to be of no interest to the authorities. He is of the opinion that great things may be hoped of the Carnegie Institution as a coming agency of reform in this direction.

The fact is certainly to be deplored that so little has been done to advance science and to encourage its disciples in the past, but, at the same time, there are undeniable signs that all branches of learning, and especially that pertaining to scientific research, will be paid due regard in the future.

An Osteopath's Defence of His Calling.

In the New York *Sun*, February 9, is a specious albeit plausible defence of osteopathy, by a professor of that art.

The gentlemen in question feigns that he is sad, because the ordinary citizen is ignorant in regard to the nature and claims of the science, and forthwith proceeds to enlighten him on the subject. He deprecates the general idea that it is something to do with the bones, and is only an emphasized massage, and claims that it is really what its name implies, a species of bone healing, and remarks that an extraordinary thorough knowledge of anatomy and physiology and a remarkably educated sense of touch are the great essentials for the osteopath.

As an example of the possession of this knowledge, and of this educated touch, and the capacity to put them into practice for the treatment of disease, the writer instances the following case:

"One woman came here with rheumatism or neuralgia. She had suffered for a long time with pain in her side, and had tried all sorts of treatment.

"I found, upon examination, that one of her ribs had in some way been forced out of normal position. Two ribs were close together, pressing on the local nerves and causing severe irritation.

"What was the common sense treatment? To get the ribs back into place, you say! Well, that's what I did!

"This is her last visit. She is cured. What was the use of giving her medicine for her blood and nerves, while the source of nerve irritation was not removed?"

However, osteopaths do not confine themselves to the cure of complaints like rheumatism or neuralgia, by such simple methods as the foregoing, but declare that diphtheria, and even cancer, can be cured by osteopathic treatment, skilfully performed.

The afore quoted writer says, "In Boston, to my own personal knowledge, several cases of cancer came for osteopathic treatment. In each case reputable regular physicians had pronounced the trouble cancer, and said that operating was the only course. The cases were cured by osteopathy.

"The patients went back to the doctors, and in each case were told that the trouble had not been cancer, because if it had, osteopathy could not have cured it. Mind you, I am not stating that osteopathy is a sure cure for cancer."

The expert in osteopathy concluded by denying that it was not so true as once, that the standards for admission into his profession were low, and brought forward the school over which Dr. Still presides in support of his assertion.

In the MEDICAL RECORD, January 25, the curriculum of a typical osteopathic college was given, and it remains only to be said that if, with such a course of training in anatomy and physiology, the graduates go forth into the world possessed of the extraordinary thorough knowledge of anatomy and physiology, claimed by the writer in the *Sun* as the great essentials of an osteopath, either the osteopathic students must be singularly gifted individuals, endowed with a marvellous facility of acquiring proficiency, in the above-mentioned subjects, or that there must be but very few real osteopaths.

The medical profession does not object to osteopaths pursuing their calling within legitimate lines, but it does stoutly object to these men infringing upon its rights and requiring to be placed upon the same plane, with the same privileges, as those who have earned their position by test examinations.

We, therefore, hastily agree with the argument of the writer in the *Sun* that the general public should become acquainted with the situation in all its bearings.

Institutions for Scientific Research.

The gift of a national institution to the United States by Mr. Carnegie for the encouragement of "investigation, research and discovery" has certain points of similarity to another splendid offering to this country many years ago.

It was in 1829 that an Englishman named Smithson, who had lived much of his life in Italy, left by will the sum of $500,000 to found at Washington an establishment for the increase and diffusion of knowledge among men.

These two gifts to science are not exactly parallel cases, for whereas Smithson was, in a manner of speaking, a foreigner, Mr. Carnegie, although born in Scotland, has lived his working life and amassed his wealth in this country, and may, therefore, be regarded as a true citizen of the land of his adoption.

The work done by the Smithsonian Institution is known in every country, and has advanced the cause of science in many different directions.

The National Library, the Weather Bureau, the

Geological and Coast Surveys and the Fish Commission all owed their inception to the Smithsonian Institution, while the National Museum, the Bureau of American Ethnology and the Zoological, still remain under its care.

The great need in America at the present time is an ample endowment for the purpose of carrying on scientific investigations, and this want the Carnegie Institution will, to a considerable extent, supply.

The scientific men of other large countries, conspicuously of Germany, are not hampered by pecuniary reasons from devoting their lives to the solution of scientific problems, and thus are enabled to gain renown for themselves and to shed luster on their nation.

Here a man who may develop a special aptitude for research in laboratory work, in writing or in both, finds that he must take up some other pursuit by which to earn his daily bread, and consequently can give but a part of his time and energy to his labor of love.

What wonder then that many become discouraged, and that only a few have the pluck to fight against adverse circumstances, and under the most unfavorable conditions to fairly wrest the secrets locked in the bosom of science.

The rich men of America have shown of late that they are beginning to appreciate the situation, and have evinced this appreciation in a practical way. The institution founded by Mr. Carnegie will greatly aid in placing America in the position, with respect to science, to which, by her wealth and brains, she is entitled.

CHRISTIAN SCIENTISTS IN GERMANY.

The cult of Christian Science, a product of America and of modern civilization, and which has flourished so exceedingly in the land of its birth, has within the past year or two, by means of its disciples, been doing missionary work in the old world.

In Great Britain the efforts of the propagators of this hybrid religion have been attended with some measure of success, particularly among the members of the leisured class, who are ever avid of something new, and which may tend to break the monotonous sameness of a life of pleasure.

In Germany the Christian Science movement has also made considerable progress with people who probably find in its tenets a similar attraction as their British brethren.

In Berlin the followers of the sect are said to be increasing at a rapid rate, and their numbers have aroused the ire, not unmixed with alarm, of the Kaiser.

The Emperor of Germany, together with the Cathedral Chaplain and Superintendent of Morals for Berlin, have expressed their determination to use their utmost influence to prevent the further spread of Christian Science. The law will not be invoked to bring about this result, but the Imperial frown will be the fate of those who continue to abide by the teachings of Mrs. Eddy, and this means much in Germany.

The announcement has been made officially that the Kaiser has issued directions that all persons who, contrary to his express wishes, will not cease from practising the Christian Science rites shall hereafter be excluded from the Court.

The Emperor of Germany is often severely criticised for his autocratic actions, but he has frequently shown that many of these are characterized by a sound and patriotic policy. His views with regard to Christian Science are an evidence that the moral and physical well-being of his people are matters near his heart.

News of the Week.

A Possible Convert to Vaccination.—A certain Dr. Immanuel Pfeiffer of Boston, who is apparently considerable of an anti, has long inveighed against vaccination—a vile operation to which he was cruelly subjected in infancy, but to which he has never consented since he arrived at years of discretion. To prove something or nothing, he recently sought permission to visit the Pest House on Gullup's Island, and the health officers, for some inscrutable reason, granted it. On his return he announced that he had exposed himself as much as possible to the disease, and, although he had not been vaccinated for sixty-five years, said he had no fears of being stricken. The Board of Health put a watch on him and kept track of him for a while, when he dropped out of sight. After some time the representatives of the Health Board discovered him in bed at his home in Bedford, suffering from a very severe attack of smallpox. It was thought he would die, but whether he did or not we have not heard.

Sudden Death of a Medical Student.—Mr. Leopold J. Koehler, a student in Cornell Medical College, fell dead in the entrance hall of the college one afternoon recently on returning from lunch with several companions. He was a senior, standing high in his class and in the esteem of his associates, and was to have been graduated next June.

Death of a Giant.—A man died a few days ago in Brooklyn who was over six feet tall and weighed 689 pounds. He was the son of a physician who retired many years ago. The cause of his death was pneumonia.

Smallpox and Politics.—Owing to the prevalence of smallpox, the City Council of Des Moines recently decided to close all churches and theaters, and to prohibit all public gatherings. The decision put a sudden stop to a bitter congressional campaign which was raging in the district, as well as to the campaign for municipal officers.

Death of One of the Separated Xiphopagous Twins.—One of the little Hindoo girls, whose connecting band was severed a short time ago by Dr. Doyen of Paris, died a week after the operation, the cause of death being tuberculosis, from which both children were suffering at the time of the operation. It will be remembered that one of the Brazilian xiphopagous twins, separated about two years ago, also died, the operation being, in her case, the direct cause.

Influenza is prevailing extensively in London, the number of cases having taken a sudden leap upward within the past week. All classes of the community are affected, and all parts of the city are equally invaded.

Fatal Accident to Dr. Traxell—Dr. T. S. Traxell, of Gallatzin, Pa., was killed on February 8, by being struck by a shifting engine on the railroad. He was a member of the Cambria County Medical Society.

Philadelphia County Medical Society.—At a stated meeting held February 12, Dr. George Erety Shoemaker delivered "The Address of the Retiring President" and Dr. George B. McClellan made a demonstration of "Anatomy in Its Application to Medicine, Illustrated by Lantern Slides and the Living Model."

Western Ophthalmological and Otolaryngological Association.—The seventh annual meeting of this society will be held in Chicago, April 10, 11, and 12, 1902, under the presidency of Dr. C. R. Holmes of Cincinnati. The secretary is Dr. William L. Ballenger of Chicago.

The Harrisburg (Pa.) Academy of Medicine.—At the annual meeting of this society, held January 31, the following officers were elected: *President*, Dr.

Hugh Hamilton; *First Vice-President*, Dr. J. Walter Park; *Second Vice-President*, Dr. D. S. Funk; *Secretary*, Dr. Thos. S. Blair; *Treasurer*, Dr. E. H. James; *Trustee*, Dr. W. H. Abbott; *Committee on Admission*, Dr. D. J. Herrick; *Library Committee*, Dr. C. H. Smith; *Sanitary and Scientific Committee*, Dr. C. C. Cocklin.

The Atlantic County (N. J.) Medical Society.—At a meeting of this society, held February 5, the following officers were elected: *President*, Wm. Edgar Darnall; *Vice-President*, T. Senseman; *Secretary and Treasurer*, Edward Guion; *Reporter*, A. B. Shimer.

The American Congress of Tuberculosis.—This congress will be held at the Hotel Majestic, this city, on May 14, 15, and 16, 1902. The *Honorary President* is Dr. A. N. Bell of Brooklyn; the *President*, Dr. Henry D. Holton of Brattleboro, Vt.; the *Secretary and Treasurer*, Mr. Clark Bell of New York. The executive officers were directed to name *Vice-Presidents* from each State, territory, province, or county, at least three from each, and selected as far as practicable from both professions of law and medicine. More than seventy-five of these have been already selected. There will also be one or more honorary vice-presidents from each State, province, and county. It is hoped to organize a museum of objects related to the study and cure of tuberculosis.

The Harvard Medical Society of New York City.—At the annual meeting of this society, held at the Metropolitan Club on January 24, the following officers were elected: *President*, William B. Coley; *Vice-President*, Myron P. Denton; *Secretary*, J. Hilton Waterman; *Treasurer*, Joseph A. Kenefick.

The Cincinnati Obstetrical Society.—At the annual meeting of this society, held in January, the following officers were elected: *President*, Dr. Julia W. Carpenter; *Vice-President*, Dr. Wm. Gillispie; *Secretary*, Dr. Magnus Tate; *Corresponding Secretary*, Dr. E. L. McKee; *Treasurer*, Dr. C. D. Palmer.

The Jefferson County (N. Y.) Medical Society.—At the annual meeting of this society, held in January, the following officers were elected: *President*, Dr. C. S. Drury, Natural Bridge; *Vice-President*, Dr. John A. Barnette, Watertown; *Secretary*, Dr. F. R. Calkins, Watertown; *Treasurer*, Dr. C. M. Rexford, Watertown.

Christian Science in Germany.—It is reported that Emperor William has had his attention called to the spread of the Christian Science cult and various forms of quackery in Germany. He has had long conferences with the chiefs of police for the purpose of devising measures to counteract the campaign there of the Christian Scientists, who have followers in the higher circles of Berlin society. It is the opinion of many persons high in authority that the treatment of the sick by the adherents of Christian Science should be made illegal in Germany.

Change in the Management of the Paterson Hospital.—The control of the Paterson General Hospital was formally transferred on February 6 from a board of lady managers to one composed of forty of the business and professional men of the city. The ladies built up the institution from a little frame structure on a side street thirty years ago to a large modern brick building. But the increase of the plant necessitated such a large current expenditure that the ladies found it difficult to raise the money, and they decided to call in business men to take charge of the finances. They will still retain their interest in the institution as an advisory board.

Gifts to Kings County Medical Society.—Dr. Henry A. Fairbairn has presented $1,500 to the Medical Society of the County of Kings, of which he is president, as a memorial to his father, the late Rev. Dr. Robert Brinckerhoff Fairbairn. A like amount was presented to the society by Dr. Calvin F. Barber as a memorial to his father, the late Dr. Isaac Henry Barber. Another gift of $500 is from Dr. Nathan T. Beers, Jr.

Consolidation of Medical Journals in Cleveland.—Plans for the amalgamation of the *Cleveland Journal of Medicine* and the *Cleveland Medical Gazette* have been brought to a successful issue. On January 22, 1902, was held the organization meeting of the Cleveland Medical Journal Company, which is composed of physicians interested in the two old journals together with a good proportion of the representative physicians of Cleveland, numbering in all forty-five stockholders. The two journals have been transferred in their entirety to the new company that will publish the *Cleveland Medical Journal*, which according to the announcement made "is to be an independent and free professional institution conducted for the good of the medical community, with no idea on the part of the stockholders that they shall ever look for dividends." At this meeting a temporary organization was formed consisting of Dr. Marcus Rosenwasser, *President*, Dr. William E. Bruner, *Secretary*, and Dr. Joseph F. Hobson, *Treasurer*. Dr. P. Maxwell Foshay was elected *Editor*, and Dr. Edward S. Lauder, *Associate Editor*.

The Orange County (N. Y.) Medical Association.—At the annual meeting of this society, held at Middletown, on January 15, the following officers were elected: *President*, Dr. M. C. Conner; *Vice-President*, Dr. F. W. Dennis; *Secretary and Treasurer*, Dr. C. I. Redfield; *Delegate to the American Medical Association*, Dr. E. D. Woodhull.

Wills Eye Hospital, Philadelphia.—Dr. McCluney Radcliffe has been appointed Executive Medical officer, a newly created position.

Obituary Notes.—DR. HENRY CORSON of Forest City, Pa., died on February 7, at the age of one hundred and eight years. He was born in Camden, N. J., March 15, 1794, and at the time of his death was the oldest person in the State of Pennsylvania. He began the practice of medicine in Philadelphia in 1802, and he was engaged in practice in Susquehanna county for seventy-five years.

DR. THOS. NEALL PENROSE, Medical Director United States Navy, retired, died at the United States Naval Hospital at Philadelphia on February 13, at the age of sixty-six years. He was graduated from the Medical Department of the University of Pennsylvania in 1858, and at the breaking out of the Civil War entered the army as assistant surgeon. He served throughout the war with the exception of a few months when he was absent on sick leave necessitated by hardships endured in a rebel prison. He entered the regular army in 1861. He was located at the Washington Navy Yard until February, 1862, when he was ordered to the United States Steamer *Harriet Lane*, which became attached to Farragut's fleet. He was under the immediate command of Commodore, afterward Admiral, Porter, and passed through the hottest battles of the Gulf. At one time all the other officers of the ship were either killed or wounded and he was taken prisoner. After a period of imprisonment at Alexandria, Va., he was exchanged, and was later ordered to the United States supply ship *Massachusetts*. After the war he saw continuous service, visiting all parts of the world. From 1872 to 1874 he was at the Naval Hospital in Philadelphia, and in 1893 he was in command of the Naval Hospital at Norfolk. For several years he was a member of the Board to examine applicants for entrance to the service and to examine junior officers for promotion. He was commissioned passed Assistant Surgeon in 1866, Surgeon in 1871, Medical Inspector in 1889 and Medical Director in 1896, being retired in 1897.

Lieut.-Col. Benjamin F. Pope, Deputy Surgeon-General, U. S. A., died at Manila, on February 14, from Bright's disease. Col. Pope was a native of New York, and first entered the military service as Assistant Surgeon of the Tenth New York Heavy Artillery, July 18, 1864. He was made acting Assistant Surgeon in the Regular Army in 1867, and promoted in the same year to First Lieutenant. From 1882 to 1886 he was in charge of the Record and Pension Division with the rank of Major. He was stationed in the Department of the East when the United States declared war on Spain, and was promoted to Lieutenant-Colonel and Chief Surgeon of Volunteers and ordered to Cuba. He was Chief Surgeon of the Fifth Army Corps at Santiago and returned to the United States in August with the troops going to Montauk Point. From that time until last April he served in the Department of the Lakes and the Department of California. He was then made Chief Surgeon of the Division of the Philippines, and on January 1 was promoted to the rank of Lieutenant-Colonel.

Dr. Thomas Neall Penrose, Medical Director, U. S. N., retired, died on February 13 at the United States Naval Hospital in Philadelphia of heart and kidney trouble. He was sixty-seven years old. Dr. Penrose was born in Philadelphia and was graduated from the University of Pennsylvania. At the beginning of the Civil War he entered the army as Assistant Surgeon and served throughout the war. From 1872 to 1874 he was stationed at the Naval Hospital in Philadelphia, and in 1893 was in command of the Naval Hospital at Norfolk. He was retired in 1897.

Dr. Jesse Meyer of Kingston, N. Y., died on February 16, at the age of eighty years. He was a graduate of the New York University Medical College, in the class of 1844.

Dr. John L. Million died at his home in Springfield, Ills., of pneumonia, on February 14, at the age of seventy-five years. He was a graduate of the Missouri Medical College, St. Louis, in the class of 1851. During the Civil War he was Surgeon of the Thirty-first Illinois Infantry under Gen. John A. Logan. He was a member of the Board of Pension Examiners, and for thirty years had been Chief Medical Examiner of the Ancient Order of Workmen. A widow and two sons, one a physician, Dr. Edward A. Million, survive him.

Dr. James H. Hine died at his home in New Milford, Conn., on February 11, at the age of seventy-nine years. His death was the result of injuries inflicted by a fall about a month ago. He was a graduate of the New York University Medical School, in the class of 1847, and practised continuously in New Milford up to his retirement a few years ago.

Dr. Henry Baker of this city died on February 14, at the age of sixty-two years. He was a graduate of the New York University Medical School in the class of 1866, and had practised continuously in this city.

Dr. Henry Corson of Forest City, Pa., died on February 8, at the reputed age of 108 years. It is said that he was the oldest person in the State. It is stated in a despatch from Scranton that he was born near Camden, N. J., on March 15, 1794. He first practised medicine in Philadelphia and later at Montrose, Hartford, Susquehanna and Forest City, all in Pennsylvania. He continued the practice of medicine up to a short time ago.

Correspondence.

OUR LONDON LETTER.

IN PARLIAMENT—THE EPIDEMIC—STREPTOCOCCAL GASTRITIS—PNEUMOCOCCIC GASTRITIS—CLINICAL EXHIBITS—THE "HEART OF THE CHILD"—NATIONAL HOSPITAL—LONDON UNIVERSITY—SOME "ASPECTS OF FRANCE."

London, January 31, 1902.

In Parliament only a few items of medical interest have transpired. The War Minister has promised that the new Royal Warrant for the Royal Army Medical Corps will shortly be published. An explanation has been offered as to the vessel with smallpox on board, which signalled "all well," but it was not stated that the commander would be prosecuted. The proposed scheme for organized research on cancer has been mentioned, but no promise of government aid has been elicited. The Home Secretary is to be asked next week if he will consult the law officers of the Crown as to the legality of the Medical Council, in their action as to medical aid societies.

The slight decrease I mentioned in the numbers of smallpox cases has been succeeded by an increase fully justifying the anticipation I expressed. Last Saturday the Chairman of the Hospitals Committee of the Asylums Board announced a decrease of 114 in the number of admissions during the preceding fortnight, a slackening of the rate of progress, which he calculated at 20 per cent. Monday's newspapers were accordingly jubilant, but the next day they had to change their tone in the face of fifty-three fresh cases, and the Asylums Board was congratulated on not having relaxed its efforts to cope with the epidemic. After I reported that the cases under treatment had reached the ninth hundred, they dwindled down to 867, at which they stood on Friday; but they began to rise again, and have continued to do so daily. Yesterday there were nearly 1,100 in the several hospitals, and seventy-eight fresh cases were notified. Thus yesterday showed the largest number of admissions, as well as the most patients under treatment. There is, accordingly, a sharp reaction from the optimism of last week, and many are predicting that the epidemic will be worse than that of 1884-5.

The Mile End Workhouse was invaded on Saturday, and out of some 450 inmates forty-two had been attacked by Wednesday, and yesterday seven more were added, including two nurses employed in the Infirmary. At this East End Workhouse the majority of the patients have been women, and it is thought that the disease was introduced by a woman lately admitted.

Among extra metropolitan outbreaks, one at Dartford—where twenty-five cases have been notified—must be regarded as serious, as the infection seems to have been taken to the shore from the hospital ships near. Moreover, there are numerous factories in the district.

Chickenpox is now made notifiable under the acts.

The King has not only expressed a wish that those employed by him should be revaccinated, but has set them the example, and, of course, many previously careless people are imitating his Majesty.

Dr. Cayley related to the Pathological Society a case of phlegmonous gastritis, due to streptococcus infection. On admission, all the symptoms of acute general peritonitis, with dilated stomach, were present. At the post mortem the stomach was found dilated, its coats thickened and infiltrated with pus from the mucous membrane, which was intact, to the peritoneum. The purulent exudation from the submucous coat showed a number of bacilli resembling the bicoli, and a few chains of streptococci; other organs normal. Dr. Cayley thought that the streptococcal infection was primary, and the bicoli a secondary effect. He said two conditions were necessary, the virulent organism and a state of membrane permitting their penetrating. As to the latter, it was remarkable how large a proportion of the patients were intemperate. He was not aware that any fatal case had been diagnosed during life, but Dörbeck claimed to have recognized a case which recovered, mainly from pus in the vomit.

Mr. Foulerton followed with a paper on pneumococcic gastritis. The symptoms in the case related were those of septicæmia with cutaneous petechiæ. At the post mortem there were numerous petechial hemorrhages into the subcutaneous tissue, "mulberry spots," on the face and neck; petechial hemorrhages on the epicardium and into the liver and kidneys, and acute fibrinous exudation over the surface of the stomach. Cultures of diplococcus pneumoniæ were obtained from the exudation, the mulberry spots and an interstitial hemorrhage into the right lung. A section of the wall of the stomach showed an exudation membrane and extensive necrosis of the glandular layer. The only similar case was Dieulafoy's case of pneumococcic ulceration of the stomach.

Dr. H. Spitta described and showed lantern slides of a [illegible] of rapidly spreading gangrene without crepitation. The [illegible] compound fracture of the four metacarpal bones and the lower third of the radius and was much contaminated with dirt, having been caused by a kite accident. The bacillus was fatal to guinea-pigs in fifteen hours. He had recovered the organism from the subcutaneous, pleural and peritoneal glands, also in pure culture from the heart blood. It resembled Welch's Bacillus aërogenes capsulatus but differed [illegible] by absence of emphysema, which occurred in infection with that.

There was a brave show of cases at the Clinical Society on Friday. Let me name some. One illustrated the value of x-rays by showing a dislocation of the scaphoid after an accident. A case of almost complete bilateral facial palsy in a lad of fifteen, who had paralysed arms and legs at five and recovered, but had never been able to move his face. There is some power in the risorius and depressor anguli oris and orbicularis oris. A girl of eighteen with bilateral cervical ribs and an abnormal bony mass at the first chondrosternal junction, giving rise to no inconvenience, illustrated by skiagram. A man of twenty with swelling of the shoulder, followed by grating in association with syringomyelia, a child with coxa vara, skiagraph shown. A lad of seventeen who, after a fall, had had separation of the epiphysis of the head of the femur, demonstrated by x-rays—a condition very difficult to determine otherwise.

Two cases of intestinal excision. One, a man of thirty—on operation in May, 1899, an obstruction was found from a hard growth around the ileo-cæcal valve. The distended hypertrophied small intestine was evacuated and anastomosed with the colon. Six weeks later the cæcum, with some inches of colon and ileum, was excised. The patient is now in good health, though the growth was carcinoma. The other case was carcinoma of the transverse colon in a woman of fifty-eight, a diabetic. Nearly five inches of colon was removed and end to end anastomosis made October 25, 1900. No sign of recurrence, patient in good health ever since. Both these cases were exhibited by Mr. Barker, the operator.

The annual meeting of the Harveian Society was held on the 16th inst., when Dr. Lees gave his valedictory address on "The Heart of the Child," a subject he feared to be much neglected. He gave important hints on physical examination in children, emphasizing gentleness in percussion. Dilatation of the left ventricle he found frequent, showing its causes are many, and perhaps the child's heart muscle specially susceptible to toxins. A very injurious cause is rheumatism, now shown to be due to a diplococcus, which has been found in the tissues of the heart. The slightest sign of rheumatism in a child calls for daily examination of the heart, on account of the disastrous effect on the patient's future. Salicylates may be freely given and leeches applied, followed by an ice bag, with precautions against chill. Ventricular dilatation, caused by toxæmia, may require strychnine and, perhaps, digitalis. The dangerous dilatation, which often follows diphtheria, is best treated by atropin, hypodermically.

A vote of thanks was accorded for the address. The new president, Mr. Watson Cheyne, was then inducted and a *conversazione* opened.

At last the National Hospital has completely rid itself of the old board. Two of the former members endeavored to get a seat on the new board and, out-voted at the meeting of governors, demanded a poll. This was carried, and they were defeated.

The Faculty of Medicine of the University has been increased from 158 to 359 members, in order to take in all the recognized teachers of advanced and intermediate medical studies. The faculty would seem to be a rather unwieldy body. It has already declared that no scheme of matriculation will be satisfactory that does not permit a wide choice of subjects.

Liverpool had a very successful meeting on Monday to promote the establishment of a university in that city. The object is to be embodied in an omnibus bill in Parliament. Already £80,000 has been subscribed towards the realization of the scheme.

Miss Cobbe has been rampaging against the doctors again and telling them how to treat cancer by "lawful and humane methods." Among other cures she recommends infusion of violets and other plans which galvanists and herbalists can suggest. This and other trash has been admitted to the *Daily News*, which, since it went pro-Boer, seems to be descending to the position of those yellow papers which pander to every form of quackery.

There is an association here for the prevention of premature burial, which held its annual meeting on Tuesday, when Mr. Brindley James, a well-known medical reformer, and ex-president of the West Kent Medical Society, gave an address on "Some Aspects of Trance." He treated his subject largely from an historical point of view, which gave him scope for interesting items.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Feb. 13, 1902.

Treatment of Inversion of the Uterus.—J. W. [illegible] reports a case in which he successfully used Thomas' method (in which the abdomen is opened and the funnel dilated, so that the uterus can be replaced in its proper position) by combining with it the Trendelenburg position. His arguments in support of this operation are that in case there are adhesions they can be separated with more care and discrimination from above; that the uterus having been replaced it is evident that the ligaments which are to support it will be elongated and weakened, and it will, presumably, be advantageous to fasten the fundus to the abdominal wall; that the uterus, having a great tendency to bleed and the patient being exsanguinated, less blood will be lost if all the manipulation can be done from above, while the patient has the pelvis elevated, and the ovarian and uterine arteries can be compressed, and that the whole operation will be cleaner, and there will be less chance of septic infection if it is not necessary to open the cul de sac of Douglas. The author's experience in the case reported was in entire conformity with what he expected, and he considers Thomas' operation with the Trendelenburg position as the operation of election in cases of uterine inversion.

Faulty Uterine Growth.—Daniel H. Craig holds that the uterine ligaments play a considerable part in these cases, and that unless proper attention be paid to them, success in treatment is much more difficult, if not unattainable. Cases of faulty growth he divides into two classes, the first comprising absence of growth, the second tardy or delayed growth. In the latter the cavity and cervix are of about equal length, and it is in this class that treatment seems to be of most value. The symptoms are deficient or absent menstruation, a childlike appearance (but, as a rule, advanced intelligence), constipation, and very sound sleeping. Treatment must be general and local. Cessation from studies, out-door life, gymnastics, and the exhibition of iron, with some laxative, constitute the main points of the general treatment. To induce growth of the organs, active (not passive) congestion must be induced, and can be secured by the intracervical application of impure carbolic acid, negative galvanism, faradism, with the use every night of two-quart, very hot douches. We must be sure that real growth and not merely swelling results. A tendency to retroversion during growth must be met by a small pessary, but when the ligaments become strong (which will be in perhaps six months after the uterus is of normal size and menstruation is regular) it can be removed.

Journal of the American Medical Association, Feb. 15, 1902.

Treatment of Obesity.—Heinrich Stern gives some elaborate dietetic tables, and discusses the necessity for limiting the amount of water taken. Concerning exercise, he says that in starting treatment most stress should be laid on passive and resistance movements. Faradism, massage, mechanotherapy—in short, all methods contributing toward the improvement of the circulation—will be followed by most beneficial results. The employment of cold hydropathic procedures, resulting in increased oxidation of fatty material, and the systematic performance of lung gymnastics, are other suitable means in the combatment of hydroplasmic obesity. For medicines, we may give for the heart, strychnine; for the blood, iron, and for the intestinal tract, beta napthalin, bismuth salicylate, or hydrastis canadensis. To relieve constipation, saline enemata, podophyllin, leptandrin, or calomel may be given. Thyroid, as a general rule, is contraindicated in hydroplasmic obesity.

Prevention of Pelvic Inflammatory Disease After Marriage.—R. B. Hall enumerates as the causes of this condition, gonorrhœal infection, exposure during the menstrual period, and septic infection following abortion. Laceration of the cervix and perineum plays no insignificant rôle in the cause of pelvic inflammation. In laceration of the cervix, with the usual laceration of the perineum and the retroversion that so often accompanies these injuries, with the endometritis following it if the injuries are not repaired, we have a condition present which may lead to pelvic disease in a large percentage of these cases. These patients all have subinvolution following their delivery, and many of them drift along until the endometritis becomes chronic or, even, a salpingitis is established. It is the physician's duty to repair the cervix and perineum within a few months after injury, before chronic endometritis and salpingitis are established, and before the uterus has been in the malposition long enough to cause extensive disease of the ovaries from pressure, to which the ovaries are always subjected after they are dragged down with the uterus in its abnormal position.

The Problems of Serum-Therapy.—J. McFarland believes that evidence is becoming more and more convincing that serum acts chemically in the cure of disease. The formation of the new substances in the blood may be explained by the "lateral-chain" theory of Ehrlich. This theory presupposes that the stimulating substances introduced into the experiment animal have the power of combining with certain groups of molecules in the protoplasm of certain cells in the body, for which they have affinity. The combination is succeeded by a regeneration of the lateral chains, which appear in a quantity slightly in excess of that existing before the stimulation of combination occurred. When more of the combining substance is now injected into the animal and the combining lateral chains again consumed, another still more copious regeneration occurs, and so on until the particular lateral chains are present in great excess, pass out of the cells into the blood where it is known to us as antitoxin. The chemical theory is supported by the following evidence: (1) The action of antitoxin on toxin always takes place in fixed proportions without relation to the quantity employed; (2) The separation of antitoxin and toxin when once mixed under proper proportions is probably impossible; and (3) The occurrence of the reaction *in vitro* is one of the best proofs that it does not occur through some indirect action of the body cells. Metchnikoff found that the introduction of any kind of cellular tissue into the body increases the ability of the blood to act destructively upon that kind of tissue. Thus, if blood of one animal is injected into another, its serum becomes hæmolytically active. If comminuted epithelium is introduced, the serum becomes ebitheliolytic in its tendencies, etc. Here we find an entirely new reaction, with an entirely new sphere of usefulness. Unfortunately, it is still too new to predict what may be the value, if any, of this phenomenon in practice. The possibility of thus attacking cancer at once appeals to us. How desirable it would be to produce a serum whose activity would be to inhibit the growth of epithelium and hasten the destruction of epithelial cells!

New York Medical Journal, February 15, 1902.

The Eye, Ear, and Throat Sequelæ of Typhoid Fever.—L. D. Brose gives several clinical histories illustrating respectively retrobulbar optic-nerve inflammation, loss of vision through hemorrhage into the vitreous of both eyes, paralysis of the muscles of accommodation, middle-ear inflammation, with involvement of the mastoid, and paralysis of the laryngeal muscles, all of which were observed as sequelæ of typhoid fever.

How to See Stomach Curvatures with the Naked Eye.—M. I. Knapp gives the following rule: The patient lies on a table in the usual dorsal position, with abdomen bare. The examiner stands at the side or at the shoulder of the patient, brings his eyes on the same level with the prominence of the patient's abdomen, and watches abdominal respiration with one eye or both. The patient breathes in a normal way, and the examiner follows certain lines which he sees move up and down with the respiration on the abdominal surface. The curvatures of the stomach will be seen distinctly as very fine lines moving under the skin with the respiration. After watching these lines for a few respirations, the observer notes where they stop each time, and marks the lines with ink. These are the lines produced by the curvatures. To corroborate, percussion is made in the following way: The closely apposed index and middle fingers of the left hand are placed on the abdomen, so that the ink line, representing the curvature, is between the two. Now the examiner percusses, very gently, over each finger, without separating them and without removing them from the place. If the line marked on the abdomen exactly corresponds with the curvature, the difference in the percussion resonance over each finger will be heard. As very gentle percussion is required, the use of the stethoscope will be found of material value. For that purpose the stethoscope does not necessarily have to be placed over the stomach, but can be placed anywhere on the abdomen. When there is a doubt as to the identity of the organ over which percussion is made one must resort to inflation of the colon.

The Management of Cerebral Hemorrhage and Its Abortive Treatment.—W. Browning advocates the use of powerful quickly-acting muscular and vasodepressants, such as gelsemium, aconite, and veratrum. These are, of course, to be used at the time of the seizure. Gelsemine is now pretty generally available, and is more convenient as well as, presumably, more exact. The author begins with a dose of from one-tenth to one-eighth of a grain, and continues in one-twentieth of a grain doses. Aconitine is his next alternative, and is efficient. His initial dose is from the one-hundreth to the one-fiftieth of a grain, the latter dose being usually required at first. For the headache he gives one of the coaltar analgenis in small doses. He adds the following "Don'ts." Don't give stimulants. Their use in such cases is most reprehensible. So often we see them freely given, notably the alcoholic. The patient is prostrated, and the lay mind naturally turns to tonics and bracers—about the worst thing that can be done. Don't resort to saline injections. During the acute stage, a limitation of fluids is in order. Don't use the depressant diaphoretics, such as ipecac, pilocarpine, or apomorphine. They tend to nauseate, an inclination otherwise too common, and, in the degree of attempts at vomiting, most undesirable. Don't prescribe digitalis. He has repeatedly seen it bring on another attack. It is a dangerous drug in any individual with a liability to apoplexy, and for this, if for no other reason, of questionable utility in nephritics. Where anything of the sort must be used, strophanthus is, in his experience, far safer. Don't resort to opiates. They are likewise contraindicated. Don't try nitrites, as their use in any form is here out of place. Don't permit any muscular exertion on the patient's part; and moving by others should be limited as much as possible.

American Medicine, February 15, 1902.

A Consideration of Twenty-eight Cases of Tuberculous Peritonitis at the Boston City Hospital, with Particular Reference to the Results of Operative Treatment.—John T. Bottomley summarizes his observations as follows: (1) We may reasonably expect cures to follow the operation in from 30 per cent. to 40 per cent. of all cases. In fatal cases the patients usually die within a few months after operation; (2) Family history does not appear to be important etiologically; but previous inflammatory affections of the abdominal viscera may have etiological significance; (3) Operation usually affords at least temporary improvement, either locally or generally, even in cases that later may prove fatal. The use of drainage following the operation should be avoided when possible; (4) Inferences as to the remote results of operation should be drawn very guardedly, if at all, from the immediate results; though in cases in which either local or general benefit does not immediately follow an operation the prognosis is very unfavorable.

One of the Etiological Factors in the Production of a Deflected and Deformed Nasal Septum and the Methods for Its Relief.—Nelson M. Black concludes that in cases of deflected septum the bony structure has become weakened primarily by traumatism, strumous or rachitic diathesis, nasopharyngeal adenoids, or the result of some of the infectious diseases of childhood; in fact, anything which tends to lessen the resisting power of the bony septum. The resistance to what the writer believes to be the natural tendency of the palatine portion of the maxilla to becoming more V-shaped, being to a certain extent weakened, it continues to arch, buckling the already weakened perpendicular septum more and more, the cartilaginous portion yielding the most (as it is the weakest and is two-thirds surrounded by the bony structure of the septum) until it occludes the nares. It must be remembered that the etiological factors which tend to produce irregularities of the superior maxilla are causative as well of deflected septum. The fact remains that in order to achieve a satisfactory and permanent result in deflected and deformed nasal septa with the high-arched palate, we should remove the active factors, the high-arched palate and acute-angled alveolar processes.

Medical News, February 15, 1902.

A History of the Army Post Exchange or Canteen.—Dunning S. Wilson reviews various reports, letters, resolutions, and discussions on this subject in order to give a correct and impartial verdict concerning it. He states that, after a patient effort covering several months, he has accumulated a mass of evidence in favor of the canteen which would make a volume of itself if it were all published. He has obtained the views of both men and women, religious workers and others, and has by every available means sought to obtain the expressions of the most conservative. Although individuals may hold various opinions, still it must be accepted that the medical and line officers of the army are without doubt in a position to judge most clearly of the benefits and evils of the canteen. The writer also calls attention to the ignorance of the general public of the meaning of the term canteen, they often thinking that it means a liquor flask carried by the soldier. This one point gives a little indication of how blindly the public follows the leader without "rhyme or reason." The general opinion of those who know, concludes the author, is that the canteen "promotes the morals, temperance, discipline, and health of the men," and that the act of abolishing it was ill-advised.

Retinal Lesions of Chronic Interstitial Nephritis.—Edward Jackson sums up these lesions under discussion as follows: (1) Alterations in the contour, size, and color of the retinal vessels. (2) Hemorrhages and hemorrhagic [illegible] changing [illegible] which sometimes go on to the removal of effused blood. (3) Retinal œdema. (4) Degenerative changes in the nervous elements of the retina and alterations in the layer of pigment epithelium. (5) Detachment of retina, which perhaps has a significance somewhat different from that of the foregoing symptoms. The retinal lesions are closely associated with vascular changes. In the great majority of cases they appear only when the prolonged high vascular tension begins to be associated with circulatory failing. The association with vascular degeneration is more constant than association with albumin in the urine, casts, or any form of any other special evidence of renal disease. Whether the vascular changes cause the retinal lesions, or whether their connection is that both spring from a common cause, the retinal symptoms take from this close connection great importance. They throw light upon the condition of the vascular system and also that of other organs of the body. They are more important both as a means of understanding the essential nature of the disease process and as throwing light on the character and course of the individual case.

The Rontgen Method in the Diagnosis of Renal and Ureteral Calculi.—Charles Lester Leonard declares that the use of the Röntgen method is essentially one of diagnosis, and that as such it should be used by professional men only. The diagnostician must possess professional knowledge, special technic, and clinical experience with this method. It is often of great service in suspected renal lithiasis, when the typical symptoms are wanting or confused, and a differentiation from diseases of neighboring organs is often impossible by the older methods. The differentiation between renal lithiasis and other forms of nephritic disease is often even more difficult. A small renal calculus may cause symptoms identical with those of incipient malignant or tuberculous disease, and, by blocking the ureter, it often causes anuria and destruction of the kidney. The Röntgen method has shown that calculi in the ureter give rise to renal colic more frequently than when they are in the calices or pelvis of the kidney. This method is of great value in cases of complete obstructive anuria. It often happens that the symptoms are so indefinite even in the case of a large calculus in the calices or pelvis of the kidney, that an absolute diagnosis is impossible except by exploratory operation or the Röntgen method. This method is the only means of differentiating between those cases that demand immediate operation and those in which medical or expectant treatment is justifiable. The chance also of error in the negative diagnosis is very slight, and the calculi that may be overlooked are so small that their final expulsion is certain.

Philadelphia Medical Journal, February 15, 1902.

What Constitutes "Septic Poisoning" in Accident Policies?—G. W. H. Kemper concludes that (1) The surgeon who is insured and receives a disabling wound, unfitting him for practising his profession, is entitled to an indemnity, whether he contracts septic poisoning or not. (2) A surgeon, while operating, may become infected through an old injury, or a new wound, the effects are the same in either instance. There is no valid reason why a policy should not indemnify alike in both cases. (3) If a surgeon cannot recover indemnity from an infection received through a sore, or an abrasion, then he gains nothing from a clause or rider attached to his general policy. In other words, the term "septic poisoning" in an accident policy is simply an aid to secure policy holders!

A New and Improved Method of Closing Vesicovaginal Fistulæ, with Report of a Case.—A. Lapthorn Smith describes the method which he employs in these cases. After careful disinfection of the vagina, the latter is incised across in front of the cervix and the bladder pushed off the uterus in the same way as in the first step in vaginal hysterectomy. In this case he reports the vagina was easily separated from the bladder with the finger everywhere except where the two edges had become united at the fistula. With the finger between the bladder and vagina, it is easy, with a few cuts of the scissors, to separate them from one end of the fistula to the other. This gives a raw edge, and obviates the necessity of cutting away a particle of either bladder or vagina. The long tear in the bladder in this case was caught with a catgut stitch at either end, taking in only the muscular wall. While these were held on the stretch the muscular wall was brought together with an over-and-over fine chromicized catgut suture going back fully an eighth of an inch on each side, but taking care not to penetrate the cavity of the bladder, or even to touch the mucous membrane. The slit in the vagina was closed with interrupted silkworm gut passed through the vagina, then through muscular wall of the bladder, but half an inch to the right of the tear in the bladder, and then through the other side of the vagina, thus inverting the bladder [illegible] to the patient's side so that the line of [illegible] and the [illegible] on the same plane as the line of the tear was. Thus the suture of the bladder was strengthened in front by half an inch of sound vagina. A catheter à demeure was left in the bladder. By this method no sutures are left in the bladder to cause irritation, which are apt to become the nucleus of calculi. The secret of the [illegible] is [illegible] the catheter à demeure [illegible] and leave the bladder at complete rest.

The Lancet, February 8, 1902.

A Case of Syphilitic Pneumonia.—The case is reported by J. G. Gibson, the patient being an adult male. The diagnosis was based on the history of the case, and the remarkable clearing up of all symptoms under anti-syphilitic treatment. A second examination showed that there had been only temporary subsidence of the original malady.

Acute Suffocative Pulmonary Œdema.—A case of this nature is reported by T. Lissman. He found that the cautious inhalation of chloroform was of great benefit, the patient being given a whiff of the drug and a whiff of air in alternate inhalations. The gasping, short nature of the breathing, and the obstruction to respiration, due to the frothy material in the air-passages, prevented any great amount of chloroform vapor being introduced into the lung. However, after from ten to thirty minutes of administration in this way, a marvelous change came over the patient. The lividity disappeared, the breathing became easier, the action of the heart became far less labored, and the respirations slowed down, the patient lying back on the pillows apparently asleep. This condition lasted perhaps for an hour, when the patient was roused and expressed herself as feeling all right. Concerning the nature of the affection, Lissman advances the following hypothesis. He says that for some unknown reason there is a spasm of the pulmonary venous or efferent system. This will account for the rapid engorgement of the lung and the subsequent extravasation of serous exudation in the alveoli, just as engorgement occurs in a limb in venous obstruction. Spasm of the efferent vessels alone would allow rapid accumulation of blood in the (afferent) pulmonary artery and its branches, and the terrific labor of the heart which is present appears to be an effort to overcome this obstruction. The continued obstruction would eventually lead to general systemic venous engorgement, hence the lividity of the face, etc.

Preliminary Note on the Possibility of Treating Mitral Stenosis by Surgical Methods.—Lauder Brunton discusses the possibility of dividing stenosed mitral valves. He has tried the operation on the cadaver and upon a living animal, and calls the attention of surgeons to the matter, for the operation, if ever done, must be done by them. The first question that arises, he says, is whether the mitral orifice should be enlarged by elongating the natural opening or whether the valves should be cut through their middle at right angles to the normal opening. He thinks there can be little doubt that the former would be the better plan, but the latter is more easily performed, and it might be sufficient to effect the desired purpose of facilitating the flow of blood from the auricle into the ventricle. He describes the knives he has used and his plan for exposing the heart, following the suggestions of Nanni of Naples. It consists in making incisions from the left edge of the sternum outwards to the left along the lower edges of the third and fifth ribs, connecting their outer ends by a third incision, and dividing both the soft structures and the fourth and fifth ribs. The window thus made is forcibly turned back on the sternum, the sternal attachments of the ribs yielding to the pressure. In this way the heart is sufficiently exposed, and the lung, being pushed back, the pericardium can be divided and the knife can be introduced into the ventricle. He has only inserted the knife into the ventricle *in situ*, and if one wished to operate through the auricle the window would probably require to be made by an incision at the lower border of the second rib, although by pulling upon the heart it might be displaced sufficiently to allow a knife to be put into the auricle even when the incision is made at the lower border of the third rib. In many experiments made for other purposes he says he has been astonished at the way in which the heart went on beating, apparently quite unaffected by pulling, compressing, or handling of any kind. In operating on the heart the knife should be introduced during diastole, as one is less likely to wound the opposite wall of the ventricle. The pericardium should not only be opened for convenience of operation, but should be left open so as to allow any blood which might ooze out through the ventricular wound to flow away instead of remaining in the pericardial cavity, for the heart has very little power, indeed, to resist pressure from pericardial distension, especially if it comes on rapidly.

British Medical Journal, February 8, 1902.

Arsenic in the Hair of Beriberi Patients from Penang.—Ronald Ross speaks of twenty samples of hair which he has lately received from beriberi patients, mostly Chinese. Dixon Mann, who analyzed the specimens, reported that six out of the twenty specimens contained arsenic, two yielded more than a trace, two yielded a trace, two a minute trace, and the rest showed none at all, This observer thinks that the question as to arsenic being a causal agent must remain open at present. The writer noted a curious apparent relation between the presence of arsenic and the duration of the cases from Penang. Nearly all the positive cases were recent and nearly all the negative cases were older. This relation may be only a coincidence, but it increases the evidence in favor of the cases being arsenical, since it suggests that the arsenic was present only at a certain stage of the disease. The Penang people work largely in tin manufactories, and are brought into close contact with arsenic.

Two Cases of Recovery after Operation for Diffuse Peritonitis from Perforation of the Appendix.—Charles A. Morton defines diffuse peritonitis as an infection far beyond the limits of an ordinary appendix abscess; it is not a general peritonitis. Early operation is of the greatest importance. The signs of diffuse peritonitis are not always distinct from those of severe localized appendicitis. In the first case here described there was little doubt that a widespread infection of the peritoneum was present. There was great pain and the face was drawn and anxious. The lower two-thirds of the abdomen was distended and very tender, and the breathing was entirely thoracic. Vomiting was persistent. Operation verified the diagnosis. The perforated appendix was removed. The patient recovered from the operation, but the last time she was seen there was still a small patch of surface granulations. The second case was more striking, for a few hours before operation the patients' pulse was only 100, there was no rise of temperature, and the tenderness and rigidity of the abdomen were confined to the region of the appendix, and there was no distention at all. Yet, on opening the abdomen, the lower part was found to be full of pus. Severe pain and frequent vomiting were the prominent symptoms, but they are often very marked in well localized forms of appendicitis. On opening the abdomen, there was seen a very large quantity of pus in the pelvis and right loin. The appendix, which was perforated, was removed, and drainage tubes were indented. The patient recovered.

Intracranial Thrombosis as the Cause of Double Optic Neuritis in Cases of Chlorosis.—C. O. Hawthorne reports this case. The patient was a girl aged seventeen years, distinctly anemic, and suffering to some degree with menstrual irregularity. She was also afflicted with diplopia and double optic neuritis. The double vision was of sudden and recent origin, and was due to a paralysis of the external rectus muscle of the right eyeball. Visual acuity was normal, there was a slight degree of hypermetropia, and the ophthalmoscope revealed considerable optic neuritis in each fundus. Later there were retinal changes in each macular region, but after a few weeks' treatment by rest and the administration of iron, the optic neuritis subsided and the ocular paralysis disappeared.

The writer presents the following argument: The simultaneous occurrence of the optic neuritis and the sixth nerve paralysis suggests a common origin; the nature and temporary duration of the two events makes it difficult to imagine any single cause capable of producing them other than an intracranial lesion; an intracranial thrombosis may certainly produce them; intracranial thrombosis is a recognized possibility in chlorosis; this patient is the subject of chlorosis; therefore it may be concluded with a considerable measure of confidence that both the optic neuritis and the sixth nerve paralysis were due to intracranial thrombosis. Thrombosis is probably the cause of optic neuritis when this occurs in chlorosis apart from other incidents having a possibly cerebral origin. The thrombosis which occurs in chlorosis is in all probability an aseptic process. One of the factors in its causation is, doubtless, a sluggish state of the circulation, due to cardiac weakness. Complete rest is imperative to prevent embolism. Care must be taken, however, not to reduce the vigor of the circulation too much. Thus, cardiac tonics, as well as iron, seem to be indicated in cases of chlorosis accompanied by optic neuritis. When a passive thrombus has been fully formed, a reasonable amount of exercise is advisable.

Deutsche medicinische Wochenschrift, January 23, 1902.

Chronic Progressive Chorea.—A Westphal reports two cases of this disease in illustration of its etiology and course. The first patient was a woman whose father was choreic, but whose hereditary history otherwise was good. The first symptoms of the disease developed after a normal puerperium five years ago. At that time she suddenly began to show violent attacks of temper, and at periods became uncontrollable. These gradually subsided, but the mental faculties progressively became impaired. Muscular twitchings soon made their appearance, and rapidly increased in intensity and extent, until at the present time all of the voluntary muscles are more or less affected. There is a nasal intonation in the voice. The knee reflexes are increased. This case especially illustrates the dementia so frequently present in chronic progressive chorea of hereditary origin. The second case was a man forty-one years of age. No hereditary history was present, and the choreic symptoms developed suddenly as the apparent result of trauma. The muscular twitchings and speech were much the same as in the first case, with the exception that the voluntary movements were not materially interfered with. These cases illustrate sporadic and hereditary forms of this disease, which are practically indistinguishable on symptomatology.

Estimation of the Quality of Human Milk by Means of Microscopical Examination.—Dr. Friedmann says that the quality of human milk may be readily judged by microscopical examination. The breast is to be milked until it flows freely, when a small drop is to be taken on a glass slide and examined under a lens giving 400 to 500 magnifications. It is seen that the fat is present in droplets of various sizes, and may be divided into three classes —large, medium-sized, and small. In perfectly normal milk the medium-sized droplets predominate; the small come next in number; while the large are infrequent, only 10 to 20 occurring on the average in each field of the microscope. Furthermore, in milk of good quality the droplets very closely approximate each other and only rarely are free spaces left between them. On a variation in these characteristics a diagnosis of the quality of the milk is made. When the large droplets are in excess of their usual number the milk is of good nutritive value, but is liable to cause digestive disturbances in the child. When there is a total reduction in the number of droplets and the small forms predominate, the nutritive value is always low. As this method of examination is easy of performance, it is recommended for routine employment in all cases, as accurate indications for treatment are to be derived therefrom and much infantile sickness may be prevented thereby.

Black-Water Fever.—M. Otto reports a case of black-water fever occurring in quartan malaria as illustrative of the theory that quinine is the causative factor of hæmoglobinuria in malaria. In this case the blood first made its appearance after the exhibition of a large dose of quinine (5 gms.). The patient had been suffering from malaria for some weeks, but quinine had not been previously taken except in one of two very small doses. The hæmoglobinuria was very pronounced, but, no more quinine being given, soon subsided. In a few days quinine was again administered, and was promptly followed by the presence of blood pigment in the urine, but this second attack was not as severe as the first. The administration of the drug was then carried on by the rectum and was not followed by hæmoglobinuria; it is probable that this was due to the small amount thus absorbed. Later renewed attempts were made to give quinine by the stomach, but whenever any considerable amount was taken hæmoglobinuria promptly occurred. The vast majority of the cases of black-water fever hitherto observed have occurred in tropical countries, and in connection with the pernicious form of malaria. The fact that this case developed in Germany, in a patient who had never been outside the limits of the country, and was plainly brought on by the administration of large doses of quinine, lends strength to the theory that this disease results from the action of quinine upon the blood of certain malarial patients.

Deutsche medicinische Wochenschrift, January 30, 1902.

Pathology of Fever.—E. Aronsohn enters into a consideration of the various steps which have led to the existing ideas concerning the mode of production of fever. It is probable that the so-called heat center in the corpus striatum is only one of a number of similar centers which regulate the heat production of the body. The acceptance of this view, however, is not vital for a correct appreciation of the pathology of fever. It is necessary in considering this subject to ascertain, if possible, the portions of the body in which the increased production of heat takes place, or, if no increased production occurs, but deficient radiation is the cause of the increased temperature, that portion of the body in which such increased temperature in that condition. A large amount of experimental work has been done upon this phase of the subject, and one after another the various body glands have been designated as such sources. Many facts, however, show that the body glands are not concerned in the production of the increased temperature in fever, and it is certain, generally speaking, that glandular activity is decreased rather than increased in the presence of elevated body temperature. Some have thought that the sources of increased temperature are to be found in the blood and originate in the metabolic changes there going on. Aronsohn's investigations show that such is not the case, for an animal in which fever is artificially produced by means of a puncture of the heat center still manifests its increased temperature when a large portion of its blood is withdrawn and replaced by decinormal salt solution. Physiology has established the fact that under normal conditions four-fifths of the heat production of the body takes place in the muscular tissues, and it seems reasonable to suppose, therefore, that in fever the source of the increased temperature is to be found in these structures. Experimentation demonstrates that such is the case. Artificial fever was produced, as above, in rabbits by means of puncture and curare injection. This substance, as is well known, simply paralyzes the terminal muscular ends of the motor nerves. By this means the metabolic changes taking place in the muscles are checked. Shortly following the injection of this substance there was a marked fall in the temperature. An animal in which the inoculation was practised previous to the puncture showed very little if any fever. The author thinks this demonstrates that the principal sources of increased heat production in fever are the muscular tissues. He believes that as the result of mechanical, electrical, or chemical irritation the heat center becomes affected so that the trophomotor apparatus of the body muscles (voluntary and involuntary) becomes damaged and the normal heat production and radiation in them altered. The type of fever thus produced will vary according to the characteristics of the factors operative upon the heat center and the various pathological conditions, if any, present in the body.

French Journals

Two Cases of Torsion of the Pedicle of Ovarian Cysts.—Capdepont and Duvergey make this report. The first patient was aged fifty-eight years, and had passed the menopause. She had noticed for two years a progressive increase in the size of her abdomen. At the time of observation she suffered from a sudden attack of acute pain in the abdomen, and the tumor in a short time doubled in volume. Vomiting began, and, on examination, there were found all the signs of an ovarian cyst. Laparotomy verified the diagnosis and revealed the cyst, which was filled with about fifteen liters of bloody fluid. The pedicle was found to have made two complete turns on its axis. The recovery was uneventful.—*Journal de Médecine de Bordeaux*, January 26, 1902.

A Mediastinal Tumor.—Ingelrans and Brassart report this tumor, which was discovered at autopsy in a young man of twenty-seven years. The patient had retrosternal pain, and on examination before death the face was found to be cyanosed, and dyspnœa was very distressing. The axillary and right clavicular glands were enlarged. The right arm was œdematous. The pulse was scarcely perceptible; there was no cardiac murmur. The breath sounds were feeble on the left side, and all the signs of a pneumonic patch were noted on the right. There was no digestive disturbance and phonation was normal. There were some dilated veins in the legs, and at these places there was a little œdema. The patient died from cardiac syncope after an attack of intense dyspnœa. At autopsy the lymphadenoma was found developed to as great a degree in the anterior as in the posterior mediastinum.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, January 26, 1902.

Discovery of Eberth's Bacillus in the Blood of Typhoid Patients During the First Days of the Fever.—M. J. Courmont points out the inconveniences of serum diagnosis, which can often not be made till late in the disease. Various observers have discovered the bacillus in the blood of rose spots, but the search for it in the blood of the general circulation has almost always proved fruitless. This is probably due to two causes. There are very few bacilli in the blood, and a culture made with a few drops only is apt to be sterile. The blood is certainly a bad culture medium for the bacillus, as it has a decided bactericidal action. The small quantity of blood that is put into the bouillon can suffice to check the growth of the microbes. Courmont takes about 3 c.c. from the vein at the fold of the elbow and puts it at once into ½ liter of bouillon. In eight cases, almost all grave it is true, he has obtained from the first and up to the twenty-third day positive cultures. He has also found the bacillus in the relapse of the fever. The writer believes that this method affords a sure and early means of diagnosis of typhoid fever.—*Lyon Médical*, January 26, 1902.

Post-Operative Hemorrhages after Abdominal Hysterectomy.—[illegible] declares that the post-operative hemorrhages are not very rare after abdominal operations. They may occur early or late. When early, they may be the result of absence of ligature, or of a slipped ligature. They may be arterial or venous. In some patients the venous system is highly developed, the veins are distended and the valves are insufficient. However, the hemorrhage is most often arterial, and its origin is easily recognized on examination. The detachment of adhesions in which blood vessels course sometimes gives rise to hemorrhage. A hemorrhage may occur eight days after the operation. These latter are rare, and may be due to septicæmic infection, or to separation of a cicatrix which exposes the blood vessels. The subperitoneal and intraperitoneal hemorrhage must be differentiated. The prognosis is very variable, according to the time of interference and the vitality of the patient. The writer then calls attention to the value of saline injections, as the danger from a large hemorrhage is not so great from the loss of blood cells as it is from the diminution in blood pressure, and in the sudden decrease in amount of volume of blood in the circulation.—*Journal des Sciences Médicales de Lille*, January 25, 1902.

Congenital Coccygeal Multiple Cysts and Fibrous Tumor.—M. F. Brennan and Choquette describe the case of a small girl of three months upon whom they operated. The tumor was pediculated, very hard, smooth, movable, without fluctuation, in the center of which was a small polyp, a little softer than the rest of the mass. The tumor was in the coccygeal region, and was the size of a small hen's egg. It was congenital and had increased in size since birth. By rectal palpation several small, smooth, elastic tumors were felt under the mucosa, although the latter was freely movable over them. The tumor was so fibrous that it almost creaked under the scalpel. The small polyp was softer. When the fibrous tumor was cut through, there were discovered several small cysts with colorless, gelatinous contents, not containing a trace of fat. When the tumor was removed there appeared on each side of the wound two osseous plaques, teratological remnants of the coccyx. There was no connection with the spinal canal. The osseous plaques were removed and the wound curetted and drained with iodoform gauze. Some days after the operation the child contracted whooping-cough and died. The wound was healed. There had been no suppuration. The tumor was purely fibrous, with no sarcomatous elements. The cysts seemed to be of the nature of the adult dermoid cyst, though not a perfect type.—*La Revue Médicale du Canada*, January 22, 1902.

The Kidney in Tuberculous Patients.—M. E. [illegible] states that the examination of urine in tuberculous patients is of the highest interest, since within certain limits it shows the condition of these organs. The quantity of urine may be modified in various ways; polyuria is most often observed, and is always the rule in amyloid degeneration. Albuminuria is the most important pathological sign furnished by urinary examination. Statistics vary as to the frequency of this symptom. It varies according to the age and according to diverse forms of pulmonary tuberculosis. Le Noir declares that it is very frequent in adolescents, falls to a minimum between thirty and forty years, it is a little more frequent from forty to fifty years, but the minimum is reached at about the age of sixty. The quantity of albumin is also very variable. It is most often moderate. The clinical form of this symptom may also vary; it may be temporary, intermittent or permanent. The amount of urea excreted is in general diminished. The elimination of phosphates is generally diminished. The chlorides are usually above normal. The toxicity of the urine is noticeably diminished. The presence of the diazo reaction of Ehrlich is, as a rule, of grave prognostic significance. Chronic parenchymatous nephritis develops chiefly in the first stages of tuberculosis. Its onset is often most insidious. Renal lesions do not appear to hasten the evolution of pulmonary tuberculosis. They are unfavorable to the general condition of the patient. They are an obstacle to forced feeding, and in some cases to medicinal treatment.—*Gazette des Hôpitaux Civils et Militaires*, January 25, 1902.

Sugar for Russian Soldiers.—The question of adding sugar to the daily rations of the Russian soldier is at present occupying the attention of the army commissariat department.

Joseph D. Bryant, M.D., President, in the Chair.

Chronic Unilateral Lymph Œdema.—By Dr. Robert Abbe.—The three cases illustrated by photograph (one of them by the patient herself) show an interesting phase of œdematous enlargement of one thigh, which contrasts strongly with œdema of other types, and is rare enough to be of interest.

Two have been watched for six and twelve years, respectively (Nos. 1 and 2), and have shown no tendency to extend to the opposite side. One has shown itself above and below the knee from the onset, but very slightly in the foot. The other confined its appearance to the thigh from the first, and only slightly involved the lower leg after many years, and never the foot.

It would be proper to class these cases as local elephantiasis of non-filarial origin, but, from their having some features resembling ordinary œdema, and from the contrasting pathology, it is better to speak of them as lymph œdema.

The hard non-pitting character of the swelling, as well as its localization, is characteristic, and its pathology is of interest.

We see by contrast: (1) A neurotic œdema in the precincts of fractures, lasting months, as in Colles' fracture of the forearm, which swells the forearm above and below the wrist. This does not involve the lymphatics apparently, and is a non-inflammatory type of disturbed innervation resulting in a serous transudation; (2) A true œdema of cardiac or renal origin; (3) A serous œdema from venous stasis associated with vascular obstruction; (4) A lymph œdema from filarial origin as in the tropical elephantiasis; (5) A chronic lymph œdema from repeated infective inflammation, as in recurrent erysipelas attacks (of which I show a photo taken by me some years since, in which case the patient had had many attacks of facial erysipelas.)

This hard lymph œdema also appears in occasional cases around necrosis infection (of which I show a good sketch in illustration—No. 3). It is also seen most typically in the hard, brawny leg with chronic ulcers and varicose veins.

I speak of these to explain the pathology which I also believe may be ascribed to the cases shown.

I will only specify one (the patient shown to-night—No. 1), whose history elucidates the matter. When I saw the patient in 1894 she was twenty-six years old. Twelve years before, she was well, and had a fall over the banisters, followed by a fever and recovery.

Shortly afterward, her mother remembers an attack of "inflammation of the bowels," with fever, and a suspicion of appendicitis.

Four years ago, she began to have this hard swelling of her lower leg above the knee, without cause. She is a music teacher, and does no work that would affect it.

Occasionally she has had pain over the appendix. I have watched her for seven years, and on one occasion found a marked tender tumor of the appendix region, which I thought entirely characteristic, but it disappeared, without operation.

My belief is that she has had an infection of the lymphatics running into the thigh and leg, by a very insidious extension, begetting an occlusive thickening, which, as time has gone on, has resulted in hyperplasia. Ziegler states that "endothelial cells of the lymphatic channels take part in the neoplastic formation and produce connective tissue."

The pathological fact, then, associated with chronic lymph œdema, is not simply a lymph stasis, but a low grade of bacterial infection of the lymphatic capillaries extending insidiously, occasionally cropping out in distant parts by migrating colonies, and inducing secondary chronic hyperplasia.

Dr. Charles McBurney said if the explanation offered by Dr. Abbe for this chronic œdema was the correct one, he was at a loss to understand why the condition was so rare, in view of the fact that many cases are apparently open to the same danger. The speaker said he had observed two cases similar to those reported by Dr. Abbe, which seemed to be dependent on operative interference. Both patients gave a history of having been operated on for hernia. One showed the evidences of a very extensive operation, including the removal of the veins and other tissues from around the vas deferens. Subsequent to the operation, the patient's penis and scrotum and the lower abdominal wall became hard and œdematous. The condition was painless, but the swelling was so extensive that it almost disabled the patient. The patient was very slow to improve.

In the other case, the hernial operation was followed by hydrocele and a characteristic swelling of the scrotum and root of the penis. In both of these cases, Dr. McBurney said, he attributed the condition to the fact that the lymphatics had been so extensively destroyed that a lymph stasis was produced.

Dr. Beverley Robinson said that in the case shown by Dr. Abbe there seemed to be considerable enlargement of the tibia, and it would be interesting to verify this by means of an *x*-ray picture. The speaker said that in a similar case which he saw many years ago, there was undoubted enlargement of the bone.

Dr. W. Gilman Thompson said he had photographs of three cases very similar to the one shown by Dr. Abbe. In two of his cases, the speaker said, the condition occurred in men; the third case was in a girl who was under his observation at Bellevue Hospital for more than two years. In all three of the cases the chief characteristics of the œdema were its firmness and unilateral localization. In the two men it was located between the knee and ankle, and in the girl it extended from the groin to the ankle. In none of the cases were the feet involved. In the case of the girl referred to, the blood was frequently examined for filaria, but without result. On several occasions there was extensive exudation from the lymph vessels in the thigh. There was much hypertrophy of the skin, which occasionally broke down from irritation, and from the abrased surfaces lymph would exude. This patient also had at times an œdematous swelling over the shoulder and neck; it was on the same side of the body as the affected lower extremity, but intermittent in character and less hard and brawny, and more suggestive of the mucinous œdema occasionally seen in myxœdema.

Dr. Thompson said that in each of the three cases the etiology of the condition remained unknown; no cause whatever could be found for the lymphangitis. Various methods were tried to reduce the œdema, such as the application of an Esmarch bandage and the use of local applications to improve the circulation, but the reduction was only temporary. In all of his cases the hypertrophy of the skin was more marked than in Dr. Abbe's case. The speaker said he was rather skeptical about the explanation of this condition which Dr. Abbe had advanced, for the same reason as that given by Dr. McBurney, namely, that these cases are so rare, whereas localized sepsis is so common. Furthermore, a localized sepsis would not explain those cases where the œdematous foci were widely separated, as in one of his cases where the shoulder and leg were involved.

Dr. V. P. Gibney referred to a case coming under his observation where a condition of elephantiasis of both limbs, but chiefly of the right, followed an injury to the right knee. The patient was a woman, well advanced in years, who fell and displaced the external semi-lunar cartilage. It was put back into place, but slipped out occasionally afterward, and subsequently she developed a [illegible] condition [illegible] years, and from that time on both legs began to be œdematous, the swelling extending down to the ankles, the feet remaining normal in size. The speaker said he was at first inclined to believe that the feet were exempt on account of the pressure of her constant wearing of shoes, and so he also had bandaged the swollen limbs, but this only produced temporary improvement.

The above case Dr. Gibney said suggested [illegible] as a possible etiologic factor. Several competent men who have seen the patient regarded the condition as a form of elephantiasis.

Dr. Edward G. Janeway said he had seen one case of that type of œdema in which the swelling appeared in various regions of the body and finally became permanent in the legs. After extensive operations on the breast for cancer, we occasionally see marked unilateral œdema which is probably not the result of a recurrent growth, but of interference with the lymph current.

The President, Dr. Bryant, said he had under observation two cases where very decided œdema resulted from operative work. In one instance the œdema came on very promptly after the operation, in the other, later. The question arises whether the condition is merely due to lymph obstruction, or whether it has a different pathology. It should be at once apparent that it is not due to obstruction from disease return, especially in the presence of thorough primary removal alike of present and prospective sites of disease.

Dr. Abbe, in closing, said that in the cases he had observed, the œdema, in the majority of instances, was on the right side. We know that the œdema caused by venous obstruction in typhoid and other fevers is four times as frequent on the left side as on the right, due, as suggested by Dr. Keen, to pressure of the right iliac artery on the vein passing beneath it, which produces a relatively sluggish venous current on the left, and thus allows bacterial colonies to lodge and initiate local phlebitis. Another point that had inclined him to the belief that the cases he had described were due to a distinct pathological infection was that in most of them the œdema began in the thigh before the lower parts of the limb became involved. A simple lymph stasis would probably manifest itself first at the distant part of the limb. In the girl he had shown the œdema had remained localized for many years above the knee.

As regards the treatment of this condition, Dr. Abbe said he had tried bandaging, electricity, applications of iodine, inunctions, and internal medication, all without effect. The speaker said he would adopt Dr. Robinson's suggestion, and have an *x*-ray picture taken.

A Case of Unilateral Right-Sided Venous Thrombosis, Associated with Cardiac Disease; Autopsy.—Reported by Dr. John Winters Brannan. (See page 291.)

Dr. Janeway said he had seen a number of these cases of cardiac disease complicated by a thrombosis of the veins of one or both of the upper extremities. This subject has recently been very thoroughly discussed by Dr. Welch in the paper which he read before the Association of American Physicians.

Dr. W. Gilman Thompson said that within the past month he saw a case of venous thrombosis involving the left arm. The patient, while apparently enjoying excellent health, suddenly complained of pain in the arm, and within an hour her arm and hand began to swell. The condition was accompanied by severe pain and tenderness in the upper arm. The œdema lasted about two weeks. The condition presented the usual appearance of venous stasis, and there was considerable difference in the temperature of the two upper extremities. At the present time the swelling has largely disappeared, but it recurs slowly when the arm hangs down. This case was especially interesting, Dr. Thompson said, on account of the utter lack of etiology. He has seen it follow grippe and various other common causes. In this case no explanation could be offered.

Dr. Thompson said he was glad to learn that Dr. Brannan had made a careful examination of the vessels in his case, and the fact that no evidences of a phlebitis were found is interesting. In the cases that develop during the convalescent stage of typhoid fever it is curious to note that they occur while the patient's condition is improving, when the heart's action is better than it has been before in the course of the disease. The speaker said he had seen it in the third week of convalescence, while the patient was rapidly gaining ground, and when a blood examination did not show any special anæmia. It is very difficult to explain some of these cases of venous thrombosis.

Dr. Beverley Robinson said that in the paper of Dr. Welch, to which Dr. Janeway had referred, the explanation is given that these venous thrombi are probably of infectious origin. The various theories that have been advanced to explain the formation of such a thrombus, such as the insufficient circulation of the blood, changes in the caliber of the vein, etc., can hardly be regarded as satisfactory, and we must go back to the idea that the formation is dependent upon some unrecognized changes in the condition of the blood itself. The speaker said it was interesting to note that in the case reported by Dr. Brannan the thrombosis was on the right side, as in the majority of cases it occurs on the left side. It is generally accompanied by some heart lesion, usually mitral in character.

A Case of Lateral Sinus Thrombosis, with Operation and Recovery.—Reported by Dr. F. P. Kinnicutt. R. G., male, twenty-six years old, was admitted to the Presbyterian Hospital, in my service, November 8, 1901. Family history unimportant. Personal history, no evidence of gonorrhœal or syphilitic infection. As a child, suffered from epileptiform attacks, which, however, were of infrequent occurrence. Attacks occurred occasionally until four and a half years ago; since then has been free from them. The patient's general health always has been excellent. Four years ago, he noticed that the veins on the lower portion of the abdomen were conspicuous and even hard to the feel, and he thinks they have gradually increased in size since. At about the same time he began to be troubled with varicose veins in both lower extremities, and underwent a surgical operation for the relief of the condition in one of the city hospitals. Recurrence of the trouble a year later, when ulcers developed, which only healed after a very considerable time. Nine days before admission to the hospital, the patient began to be troubled with headache, especially localized over the right temporal region, and also with pain in right eye. The headache persisted, and all attempts to relieve it were without avail. The patient became apathetic and dull. A local application, probably containing atropine, as patient was told it would dilate the pupil, was used for the eye.

Physical Examination on Admission to Hospital—The patient is a well-nourished, muscular man. There is marked hebetude, the speech is slow and thick, and the preceding history could only be obtained from the patient's wife.

The pupils are unequal, that of the right eye being dilated and not reacting to light. The left reacts normally. There is a slight rigidity of the posterior cervical muscles, especially of those of the right side. Firm palpation over the mastoid portion of the right temporal bone elicits much pain over a very localized area. There is no œdema over this area. There is no discharge from the ear. Examination with the speculum reveals a duskiness of the drum membrane, but the natural concave surface is preserved. There is a little redness of a portion of the outer wall of the external canal. The pulse is regular, slow, of fair force. The temperature (mouth) 100° F.

Examination of the various organs elicits only negative signs. There are large areas of dark pigmentation on the anterior and inner surfaces of the right leg, evidently the seat of old ulcers, and similar conditions are noted over the lower portion of the left leg. The left internal saphenous vein is varicose throughout its entire course; the right from below as far as the knee. The superficial external iliac veins on both sides are conspicuous and greatly dilated, the condition being especially marked on the left side of the abdomen. At various points along the course of both veins, the vessels have the feel of hard cords, and at other points they have the beady feel present in advanced endarteritis deformans. The superficial veins elsewhere are not enlarged. There is slight œdema about the ankles.

The walls of the accessible arteries are not appreciably thickened.

The urinary examination is negative. The leucocyte count amounts to 9,500.

During the three subsequent days the patient grew steadily worse, although the local signs described remained unchanged and no new ones were developed. The hebetude became gradually deeper, until the patient lay in a partial stupor, from which he could be aroused with difficulty. The temperature gradually rose to 101.5, the leucocyte count slightly rose (10,000). Culture from blood showed no growth. At no time was Kernig's sign present.

A thrombosis of the right lateral sinus was believed by me to be probable, and my colleague, Dr. McCosh, agreed with me that an exploratory incision was indicated, and on the fourth day after admission the right lateral sinus was exposed by Dr. McCosh. It was found to contain a solid thrombus, an inch in length. It was carefully squeezed out, removed with a curette, and a probe was then easily passed along the sinus for nearly two inches in both directions. There was no evidence of disease of the mastoid cells.

On the day following the operation the patient's mental condition had improved. From this date all symptoms gradually improved, and on the 23d the patient's condition was practically a normal one. On December 15 the patient was discharged from the hospital cured.

He has since returned to his work, and his health is in all respects excellent.

Dr. Kinnicutt said that the evidence upon which the diagnosis of a probable sinus thrombosis was based by him was the hebetude of the patient on admission gradually deepening into stupor, the pain localized over the mastoid portion of the temporal bone, a localized area of sensitiveness on firm pressure over the same site, the evident disturbance of circulation in the drum membrane without the signs of acute inflammation, and finally the presence of thromboidal and sclerotic veins in other parts of the body. The absence of any marked rigidity of the cervical muscles, the character of the pulse, the absence of any symptoms pointing to irritability or of pressure, also the absence of Kernig's sign, which, as a rule, obtains in cases of meningitis, except perhaps of a very localized nature, led him to exclude the diagnosis of a meningitis. The absence of œdema over the mastoid portion of the temporal bone, of ear symptoms beyond the duskiness of the drum membrane, which preserved its natural concave surface, led him to doubt the origin of the trouble in a middle-ear lesion. It remained to consider whether the sinus thrombosis was of the form designated as autochthonous or marantic thrombosis, or was due to a true lesion of the vein. The sclerosis of the external veins was most interesting and of a far more pronounced form than he had before observed. Sclerosis of the veins is comparatively rare, and little is contained in the literature on this subject.

The absence of any of the conditions usually associated with marantic or autochthonous sinus thrombosis, a case of which he had reported to the society during the past year, led him to believe that in the present instance the thrombosis was due to a true lesion of the sinus walls.

Dr. Robinson said that Dr. Kinnicutt deserved much credit for making his diagnosis in this case, but the question arises whether these patients are, as a rule, particularly benefited by operative interference. The plugging of the sinus does not seem to cause any special symptoms, and if that is so, what is the use of removing the thrombus?

Dr. Abbe asked Dr. Kinnicutt to what he attributed the relief of the cerebral symptoms, as no pus was found?

Dr. Kinnicutt said it had been shown by experiment that it was possible for an extensive thrombosis of the cerebral sinuses to exist without causing symptoms, and that the symptoms when present were probably due to an extension of the thrombus of the sinus into the cerebral veins, resulting in localized destruction of the cerebral tissues by hemorrhage, softening, and, in some instances, in subarachnoid and ventricular effusions.

In reply to Dr. Robinson, Dr. Kinnicutt said that in this particular case, at all events, an operation was clearly indicated. The patient was rapidly growing worse, and the speaker said he did not feel satisfied that everything possible had been done without an exploratory operation. In similar cases he would pursue the same course.

Intermittent Claudication Due to Obliterating Arteritis.—Reported by Dr. Charles L. Dana. (See page 290.)

Dr. Kinnicutt asked if there was any appreciable thickening of the vessel walls in the case reported.

Dr. Dana replied that evidence of arterial sclerosis was present, but not marked. The heart's action was feeble, but there was no organic trouble.

Dr. Kinnicutt said he saw no reason why this condition should not occasionally occur in cases of general arterial sclerosis, with myocardial trouble. Clinically, the speaker said, he could recall cases of this kind.

Dr. Dana said the most common examples of this condition were the cases of temporary limping due to a transient paralysis of one leg.

Dr. V. P. Gibney asked whether the condition was anything like the limp sometimes observed in children who have a cardiac lesion resulting from subacute rheumatism? This could hardly be so, however, as we do not often see sclerosis of the vessels in childhood. In those patients it is more apt to be due to a central lesion resulting from an embolus.

Dr. Abbe asked whether these patients had any general symptoms or any evidences of uræmia? From the report given by Dr. Dana, the condition was not unlike that of angio-spasm of uræmic origin sometimes observed in the course of nephritis.

Dr. Thompson said it seemed curious that so large an artery as the femoral could completely occlude itself by a spasm. Experimentally, it is impossible to close it by any kind of irritation; it can be narrowed down to perhaps one-half its size, but cannot be entirely occluded.

Dr. Thompson said that, in listening to Dr. Dana's paper, the question had suggested itself whether cases of transient hemiplegia belonged to this same class. The speaker recalled the case of a physician, who, while seated at luncheon, suddenly became unconscious. His right side was found to be paralyzed, and several clinicians who saw him pronounced the case one of right hemiplegia. After remaining in a state of complete coma for several hours, he suddenly recovered consciousness, and was at once able to make use of the affected arm; a few minutes later, he jumped out of bed, and turned down the light, because it annoyed his eyes. His aphasia did not disappear until the following day.

Dr. Thompson said he had seen several similar cases of complete unilateral paralysis where recovery took place within a few hours, and which obviously could not have been due to a thrombus or embolus.

Dr. Dana, in reply to Dr. Thompson, said that pulsation of the femoral was present, but no pulsation of the popliteal, posterial tibial, or dorsali pedis could be felt.

These arteries were probably affected and thickened, and the lumen small, and it does not take very much spasm to completely close them. When this occurs it does not produce absolute paralysis of the leg, but simply inability to walk.

Dr. Dana said that the cases he had described were unlike those of acute temporary hemiplegia of uræmic origin. In the latter type the lesion is cerebral, and is due to local asphyxia of some of the cerebral vessels. They are quite commonly observed in connection with syphilis and paresis, but the distinction between them and the peripheral type is considerable. In the latter there is an absence of palsy, stiffness, vasomotor disturbances, and a good deal of pain due to the obstructed circulation. In both types the claudication is due to a more or less complete shutting down of the arteries, but the ordinary cases we see are examples of cerebral claudication, while these are peripheral.

A Case of Appendicitis with Unusual Manifestations.—Reported by Dr. Charles McBurney. The patient was a young lady, twenty-four years old, who, during the middle of last summer, had an attack of illness which was recognized by a very competent observer as one of moderately acute appendicitis. It subsided in the course of a week, and the patient remained perfectly well until ten days ago, when she again began to complain of intra-abdominal pain. She was seen in consultation with Dr. Kinnicutt, and because of her rising pulse and temperature an early operation was deemed advisable. The peculiarity of the case consisted chiefly in the location of the pain or tenderness. Over the ordinary situation of the appendix there was absolutely none. The belly was flat, and as one palpated upward in the right loin, the tenderness became more and more intense up to the right hypochondrium, where the maximum tenderness existed. On passing the left hand under the loin and behind the right kidney, one could very distinctly lift up a small inflammatory mass, evidently that of an inflamed appendix involving other tissues. It was perfectly clear that it was not the kidney, but when the kidney was raised it also lifted this inflammatory mass.

With these facts in mind, an incision was made a good deal higher than the ordinary incision for appendicitis. The colon was found and drawn upward out of the wound in order to bring the base of the appendix into view, but instead of drawing up the caput coli, Dr. McBurney said he found that he was drawing the transverse colon into the wound. This was thereupon put back, and the intestine pulled down from above, and this very soon brought the inflammatory mass into view, but it was necessary to enlarge the external wound before access could be gained to it. When the inflammatory mass was brought out through the wound, it was impossible to recognize in it any portion of the appendix, and yet there was no intervening tissue. One could feel an indurated, small tumor, but could not make out any outline. Eventually, by cutting through a covering of peritoneum, the appendix was made out; it was completely buried in the wall of the colon and covered by a remnant of fœtal life in the form of a very complete peritoneal sac. This had to be incised before the appendix could be dissected out; then it was found easy to remove it, as it was distended with fluid. The wound was closed without suturing, and the patient made an uneventful recovery.

The appendix, on inspection, proved to be a closed cyst, which was filled with pus and fluid feces and a single concretion. The sac was considerably distended by the fluid which it contained, and on its inner wall were two necrotic spots, but it was not perforated.

Dr. McBurney said that Huntington, in his description of the fœtal anatomy, mentions the fact that the caput coli is sometimes found in this abnormal situation. Ordinarily, it undergoes a change of position and occupies the lower region in the right iliac fossa, where we usually find it. Dr. McBurney said he had met with this reversed condition of the parts before, but had never recognized it as such.

Dr. Abbe said that one must understand the variations of the colon in order to meet successfully these emergencies in a certain number of appendicitis cases. The speaker said he had seen one similar case.

Dr. Kinnicutt said the case reported by Dr. McBurney was an illustration of the seemingly general tendency toward appendicitis occasionally observed among members of the same family. The case reported was the third case of appendicitis occurring in the patient's family.

Dr. Bryant said that upon two occasions, in operating for appendicitis, he had been similarly misled by a prolapse of the transverse colon; a general intestinal prolapse was not evident in either instance.

Dr. Bryant exhibited an appendix which he had removed that day from a patient who had suffered from two attacks of appendicitis during the last six weeks. The appendix was removed about three weeks subsequent to the second attack, when there were no symptoms present. The lower end of the appendix was apparently a closed sac containing abundant fluid muco-purulent contents. This reference emphasizes in no uncertain manner the subtle danger attendant on a quiescent appendix, thus impressing the wisdom of operative practice in an interval having no apparent local or general evidence of appendicular involvement.

THE NEW YORK PATHOLOGICAL SOCIETY

Anniversary Meeting, Held January 8, 1902.

Edward K. Dunham, M.D., President.

The Value of the Eosinophile Count in the Differential Diagnosis of Human Blood.—Dr. Orrin S. Wightman was the author of this paper. A number of blood smears from different animals constituted the material for the study forming the basis of this communication. The smears were stained with Ehrlich's tri-acid stain. There was reason to believe that the home of the eosinophile cells was in the bone marrow. The normal percentage of eosinophile cells in the human blood varied from one-fourth of 1 per cent. to 4 per cent. The possible causes of eosinophilia were very varied. The physical status of animals would be expected to bear a distinct relation to the proportion of the kind of cell present. In the author's study 500 cells were assumed as a standard. Blood from the sheep, pigeon, gray rabbit, calf, and goat was examined. In all these animals the percentage of lymphocytes was rather high, varying from a minimum in the goat of 34 to a maximum of 97.6 in the pigeon. These animals also showed a rather small polynuclear count.

Dr. F. C. Wood said that he had been much interested in tracing a possible connection between a large number of eosinophiles in the blood and tapeworm in the stools. He had examined cases containing both round worm and tapeworms, and had found no increase in the eosinophiles, though such increase had been observed in a number of cases. Quite recently he had seen a case in which a considerable increase in the number of eosinophiles in the blood had been observed, and had led to a probable diagnosis, though no segments of worm had been passed. Later, fragments of the worm had been passed. The percentage of eosinophile cells at this time was 20 per cent.; after the worm had been removed, the percentage fell in the course of a few weeks to 8 per cent. One case of Bothriocephalus latus had shown no eosinophile increase, though the stools showed a very large number of Charcot-Leyden crystals, which are usually seen only in connection with an eosinophilia.

In all cases of asthma which he had examined, the percentage of eosinophiles had been high, usually about 20.

Dr. T. C. Janeway said that last year he had made an interesting observation, *i. e.* the occurrence of a moderate eosinophilia, 5 or 6 per cent., in cases of vaccination; but further study had shown that this was by no means a constant phenomenon.

Dr. L. A. Conner said that in a case of severe secondary anæmia dependent upon the presence of an intestinal parasite, anchylostoma duodenalis, and occurring in a young boy from Brazil, he had found an eosinophilia amounting to 8 or 12 per cent.

Dr. A. J. Lartigau spoke of the presence of eosinophiles in the serous membrane exudates. During the last six months, Dr. Moschcowitz had made cytological examinations of these exudates, and in a certain proportion of these cases, particularly of pleuritic exudate, a very striking eosinophilia had been noted. In one case in particular the cells were almost exclusively eosinophiles, but in that instance the etiology of the pleurisy could not be established. The differential count of the blood showed a very slight increase in the eosinophiles, but it was not proportionate to the increase in the exudate.

Dr. Wightman said that one should be mindful of the effect of the personal equation in blood counting, and that in many cases the observer was in doubt as to whether the cells were eosinophiles or polymorphonuclear cells. He had used methylene blue and eosin as controls to the tri-acid stain.

Multilocular Echinococcus Cyst of the Liver.—Dr. L. T. LeWald presented this specimen. It had been presented at the last meeting, and had then been described as a primary carcinoma, there having been only a microscopical examination of a frozen section. Further examination showed that there was not sufficient evidence on which to base a diagnosis of carcinoma. There was, it was true, a slight alveolar arrangement, but no true epithelial cells, although there was an infiltration with small round cells, and there were many areas of degeneration. At the suggestion of Drs. Oertel and Dunham a more careful examination had been made of different parts of the tumor, and this showed a structure which answered very well the description of a multilocular echinococcus cyst of the liver. Three cases of this kind had been reported in this country: one by Prudden, in 1873; one by Gardner Dean, in 1877, and one by Oertel, in 1899. In all of these cases, and also in the present instance, the growth had occurred in a foreigner. The symptoms had been quite similar in all the cases. In Prudden's case a diagnosis of hepatic abscess had been made, while in Oertel's case a provisional diagnosis of echinococcus cyst of the liver had been made prior to operation. The tumor in the case presented occupied all of the left lobe of the liver, and was extending peripherally. It was broken down in the center, while the border was made up of dense fibrous tissue. On close examination, one discovered a number of small translucent areas, and these, on microscopical examination, showed the presence of small cysts. The other details of the case had been given at the last meeting of the society.

A Case of Cutaneous Pigmentation, with Lesions in the Adrenal Bodies.—Dr. Harlow Brooks reported this case. The subject was a woman of forty-five years. The previous history could not be obtained because of the mental state of the patient at the time of her admission to Bellevue Hospital. Physical examination showed her to be poorly nourished; there was quite marked œdema of the extremities, and over the thigh and entire trunk the skin was deeply pigmented. The patient was almost in a state of collapse. The pulse was small, rapid, and weak. The lungs were apparently healthy. The liver extended two fingers' breadth below the free border of the ribs. On the day after admission, the temperature rose, and the usual symptoms and signs of pneumonia developed. Examination of the urine justified a diagnosis of chronic interstitial nephritis. Examination of the blood showed a condition of extreme primary anæmia. An autopsy could not be obtained until the day after her death, and hence a histological examination of the nervous system was not made. There was a dark brown, glossy pigmentation of the skin on the trunk of the body, and extending down to the middle third of the forearm, and on to the thighs. The backs of the hands were also slightly pigmented. The skin showed many scars from the bites of parasites, and these scars, where they appeared on the pigmented areas, were distinctly white. The skeletal muscles were light brown and very soft. An obliterative subacute pericarditis was present, and the left pleural cavity was obliterated by adhesions. The myocardium was very soft and light. The subcutaneous fat and that over the heart presented a very peculiar color somewhat like that of lard. The thyroid gland was noticeably small, though apparently normal in structure. The lymph nodes of the neck were markedly anthracotic. The left lower lobe showed a pneumonic consolidation and a quite general acute miliary tuberculosis. The liver was enlarged and extremely fatty. The pancreas showed no definite change. Aside from anæmia, the gastro-intestinal tract showed nothing of importance. The left kidney was a typical large white kidney. The right kidney was very small, and its parenchyma was entirely replaced by a production of fibrous tissue, which appeared to enclose old tubercles. The right adrenal body presented a peculiarly pink cortex, and the same was true of the left adrenal, though the latter also presented certain fatty areas in the cortex. On microscopical examination, the peripheral lymph nodes showed no differentiation between cortex and medulla. There was an infiltration with cells, whose nuclei showed a tendency to degeneration. Sections of the peculiar fatty tissue showed no microscopical abnormality. In the voluntary muscles most of the fibers were normal, but some were swollen and degenerated. There was a marked fatty infiltration of the heart muscle, and there was increase of cell pigment. Occasional areas of small round cell infiltration were also found in the myocardium. The stomach showed the lesions of a chronic atrophic gastritis. Almost the entire structure of the lymph nodes was converted into tuberculous tissue. The parenchyma of the liver was almost completely replaced by fat. The left kidney showed acute parenchymatous nephritis and extensive fatty degeneration. Sections of the right atrophic kidney showed the atrophy to have followed an old tubercular process. Numerous sections from the suprarenal gland showed the changes to be about the same on both sides. The capsule was not thickened, but there was a general and very marked augmentation of the connective-tissue framework. The individual fibrillæ were swollen and œdematous. The walls of the blood vessels were somewhat thickened. The vessels were moderately congested, and there were a few extravasations of blood. As a rule, the acini were made up of normal cells, and such alterations as were found involved the whole acinus to about the same degree. There was extensive fatty degeneration in both the medulla and cortex. The pigmentation was quite noticeable. In the medulla and throughout other portions were occasionally found cells which were from two to four times the normal size. Other cells with large chromatic nuclei were found huddled together. Around some of the blood vessels small adenomatous masses were found. In true Addison's disease the pigmentation was usually found in the more exposed parts of the body, whereas, in this case, these areas were the least pigmented. It was very probable that the subjective history, if it could have been obtained, would have been very similar to that of Addison's disease. The lesions of the viscera corresponded rather closely with many cases of Addison's disease, but exposure and the destitute state of the patient would explain these. Tuberculosis of the adrenal might occur without either subjective or objective signs of Addison's disease. He had reported such a case to this society some years ago. The speaker said that he did not look upon this case as one of Addison's diseases, but rather as an example of vagabond's disease with secondary changes of the suprarenal glands, resulting finally in an atypical skin pigmentation.

Dr T C **Janeway** said that Dr Brooks had presented a very careful and critical report of this case and it seemed wise not to call this Addison's disease as the clinical picture certainly lacked some important features of that disease. There was no pigmentation on the mucous membranes and on the exposed portions of the body. Again, the extreme anemia was not at all characteristic of Addison's disease. In two cases of that disease that he had seen very shortly before death the secondary anemia had not been at all marked, and the literature consulted at that time had not made anemia a prominent symptom. The chronic tuberculosis and alcoholism in the case under discussion seemed to explain the lesions found, though an early stage of Addison's disease could not be excluded.

Dr E **Libman** said that in one case of Addison's disease, seen two years ago, there was every evidence of anemia. This case was examined post mortem, and the diagnosis confirmed by finding tuberculosis of the adrenals. In another case there was the usual pigmentation, and the blood picture was that of pernicious anemia. There was no autopsy on the second case.

Dr **Conner** asked Dr. Brooks if he thought the changes seen in these adrenals were very uncommon—in other words, if there had been no pigmentation of the skin, would the changes in the adrenals have led him to suspect anything especially abnormal? He asked this question because of the great variations often observed in adrenals which were apparently normal.

Dr. **Warren Coleman** said that he had seen three cases of Addison's disease, and he had also examined microscopically many suprarenal capsules. This study had impressed him with the difficulty of telling much about the adrenal unless this body was obtained very soon after death, was very carefully hardened and cut into sections, and very carefully examined. On gross examination in many of these cases the whole of the medulla and a portion of the cortex were converted into an apparently colloid material. If the hardening were carried on in alcohol or formalin, this could not be well made out under the microscope. Personally, he was not disposed to look upon the changes noted in the adrenals as the cause of the pigmentation in the skin. In one of the cases of Addison's disease that he had seen, in which the diagnosis had not been made during life, he had made the autopsy. The patient had been sent to Bellevue Hospital from the Chambers Street Hospital with a diagnosis of chronic constipation, and although under observation for several weeks at Bellevue Hospital, there seemed to be no reason to change this diagnosis. At the autopsy both adrenals were found completely destroyed by a tubercular process. One of them was considerably larger than normal, and the other only slightly larger than normal. The latter was calcareous, and the former was caseous, and neither showed a trace of adrenal tissue. In this case there was no pigmentation whatever. He was disposed to look upon the pigmentation in Addison's disease as the result of some lesion of the ganglia of the sympathetic. Dühring had shown that a lesion of the sympathetic ganglia might produce pigmentation without causing Addison's disease. He had seen several cases of vagabondism in which there were areas resembling vitiligo, and the distribution was almost identical with that found in Dr Brooks' case. The malnutrition and the previous depressing influences of the tuberculosis seemed quite sufficient to explain the pigmentation in this case.

Dr **Carlin Philips** said that he had studied a number of adrenals, and was therefore deeply interested in the case just reported. With the exception of pigmentation, the case presented no symptoms of Addison's disease. The microscopical study of sections of the adrenal was most important, and should be made more generally a routine measure. It was very common to find artefacts. Some of the changes described by Dr Brooks were undoubtedly pathological—the changes about the vessels, the increase of connective tissue and the atrophy and disappearance of the glomeruli were not found in normal gland. The alterations in the staining of the nuclei and the change in the fat contents might easily be confounded with changes found in the normal gland.

Dr P. A **Levene** said that the case was highly interesting because it added to the doubt which already existed as to the relation between pigmentation of the skin and disease of the adrenals. This case showed both the pigmentation and the changes in the adrenals but neither presented the appearance characteristic of Addison's disease.

Dr **Brooks** said that the pigmentation was very profuse and covered the entire trunk, and was altogether different from what he had formerly seen in vagabondism. He thought his attention would have been attracted by the changes in the adrenals, even though skin pigmentation had not been present. He knew of no satisfactory and definite description of the normal structure of the adrenal, and it was quite true that artefacts were apt to be present. Allowing for imperfections in technique, he still had yet to find any such defect which would cause myotosis in the nuclei of the cells, and he had yet to find large giant cells containing atypical mitoses in normal adrenals. He thought that ordinarily marked changes in the adrenal bodies were accompanied by marked changes in the skin. He doubted if the tuberculosis was a prominent factor in the production of the pigmentation. There were very few chronic tubercles present in the lungs of this patient.

Primary Pigmented Sarcoma of the Fourth Ventricle.—Dr. J. H **Larkin** presented this tumor, which had been removed from a male, fifty-six years of age. There was a history of paralysis of the external rectus and abducens with facial atrophy on the left side. There was no headache or vomiting at first, and no typical picture of such a growth in the early stage. Subsequently the paralysis became well defined, and examination of the eye showed marked choked disk. For three months the man went around, although he occasionally fell in the street and temporarily lost consciousness. Finally the vertigo was so pronounced that he was compelled to remain home constantly, and he eventually died of secondary pneumonia. At the autopsy two tumors were found. On opening the brain he found a tumor, a psammoma of the pineal gland, and on the floor of the fourth ventricle was a very small pigmented tumor at the anterior fovea. On the floor of the ventricle was a very large engorged vein. Sections of the tumor were exhibited under the microscope. The periphery showed the presence of blood pigment, while in the center there was a yellow pigment (melanotic) tumor, composed of polyhedral cells and stroma with many new-formed blood vessels.

Abscesses of the Mesentery with Secondary Thrombosis of the Mesenteric and Portal Veins.—Dr. E **Libman** said that out of forty-eight autopsies on cases of appendicitis he had found in six suppurative lesions of the mesenteric veins or the portal vein. In four of the cases there were multiple abscesses of the liver. One of these appeared on gross examination to be merely fatty, but microscopical examination proved the presence of pus cells between all the cells. Dr. Libman presented a specimen showing multiple abscesses of the mesenteric nodes with secondary purulent thrombosis of the mesenteric and portal veins. The patient had been admitted on December 14 for appendicitis, having had two chills prior to his admission. At the operation there were found an ulcerated appendix and a mesenteric abscess. The patient did not do well after the operation, and although abscesses in the liver were suspected and searched for, none could be found. Cultures from the case showed the presence of streptococci. A search through the literature showed that this class of complications of appendicitis had occurred in his experience almost twice as often as in the reported experience of others. Perhaps this was to be explained by the fact that most of the other cases had occurred before the days of frequent operations for appendicitis, and when many cases now considered as not being very severe died. Ordinarily a case of suppurative thrombosis of the portal vein with multiple abscesses was looked upon as fatal, but Dr. Libman reported a case which seemed to refute this notion.

Dr. F. C. Wood said that in those cases in which a cure had been observed to take place spontaneously, the infection might be due to a low-grade colon infection, such as is seen in cases of biliary cirrhosis. The invasion of the colon bacilli in the cirrhosis cases only determines small areas of necrosis and pus formation, and may go on to a cure.

Dr. LIBMAN said that in the case he had referred to, in which the abscesses were healing, the infection was found to be due to streptococci, and the case at first appeared to be very virulent. The lesions in the portal vein and liver showed almost complete organization, the fatal issue being due to a large abscess in the mesentery. Specimens from this case were shown .

Bilirubin Crystals in Urine.—Dr. T. C. JANEWAY exhibited under the microscope bilirubin crystals from the urine of a case of obstructive jaundice of five days' duration. This was the first time that he had met with these crystals under such conditions.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 27, 1902.

CHARLES N. DOWD, M.D., FIRST VICE-PRESIDENT, IN THE CHAIR.

Sterility Due to Faulty Conditions of the Endometrium, and the Best Methods of Treatment.—Dr. W. GILL WYLIE took up this part of the discussion of the general subject of sterility. He said that his first experience in this field had been with Dr. Sims' method of dividing the cervix anteriorly and posteriorly. He had soon learned that in a large proportion of cases the desired patency of the canal was not established in this way, but, on the contrary, that the contraction incident to the healing process tended to close the canal. Further study showed that an important factor in the production of sterility was imperfect development of the uterus. This was particularly noticeable among the better classes, probably because many weaklings in this class live to adult life, while among the poor they die before reaching puberty. Another reason was that among the well-to-do the growing girls were often compelled to study so much that the mind was developed at the expense of the body. He had come to look upon the imperfectly developed and anteflexed uterus as an organ, the seat of catarrhal inflammation, and he had, therefore, suggested that these cases be treated by complete divulsion of the cervical canal, curettage, and, if necessary, the application of some antiseptic, and then keeping the canal open for a length of time. Anything which produced a scar must necessarily interfere with the function of the glands and follicles, and hence should be avoided. Moreover, the uterus was different from an ordinary sinus in that it was controlled by a very powerful sphincter. Eighteen years ago he had experimented with various methods of keeping the canal patent. After many trials he had discovered that a drain made of hard rubber was the best. A large, patulous uterus did not, of course, need such a device; it was in the imperfectly developed, indurated and hyperplastic uteri that this device was required. It was essential that whatever was used, it should secure good drainage; if it acted at all as a plug, it would tend to force the secretion of the diseased uterine cavity back into the tubes. His practice has been to leave in the tube for a week or ten days. This treatment would usually relieve dysmenorrhœa, and would often cure the sterility, although sometimes it would be necessary to repeat this treatment. Even under such treatment, one should not expect to get good results immediately. Increasing experience had shown him that the tube could be safely left in for several weeks. The patient should be kept in bed for from five to seven days, and then might be allowed to go around. No douches should be given, but the vulva should be kept scrupulously clean. Instead of keeping the tube in place by a gauze packing, a modification of the Albert Smith pessary should be employed. It should be remembered that if the uterus were prevented from retroverting, the drainage tube could be kept *in situ*. In some instances ectopic gestation had followed this treatment for sterility, and he was inclined to think that perhaps disease of the endometrium had more to do with ectopic gestation than was generally supposed. Cases of gonorrhœal endometritis were not very hopeful, for it was almost impossible to eradicate by any means the disease, and get the lining membrane of the uterus in a sufficiently healthy condition to allow of the occurrence of pregnancy. In some cases of sterility the unhealthy condition of the endometrium was the result of vascular conditions set up by the presence of small fibroids in the anterior wall of the uterus. Still another cause of sterility was a gouty or uric-acid diathesis, especially when occurring in stout women. By laxatives, reduction of the fat, and treatment directed to the general health the sterility could sometimes be overcome.

Sterility Due to Faulty Conditions of the Uterus, and the Best Methods of Treatment.—Dr. EDWARD J. ILL of Newark, N. J., read this paper. It was well, he said, to bear in mind that sterility was a symptom of many conditions, and not in itself a disease. At the outset a careful inquiry should be made as to the health of both husband and wife, and their relations to each other, and it should be known positively that the semen was normal before instituting treatment of the wife. The uterus should be the last organ thought of in considering the question of sterility. The causes of sterility were either mechanical or pathological. Among the former were the various displacements of the uterus, not forgetting retroposition of the uterus, extreme lateral displacement, and changes in position resulting from cicatricial contraction near the base of the broad ligament. Inflammatory diseases of the cervix, erosions, and cystic degeneration were important causal factors. Among the pathological causes were imperfect development of the uterus, atrophy occurring near the menopause, and the presence of various neoplasms. Fibromata certainly played an important part in the production of sterility. It was well known that 10 per cent. of marriages were sterile. A certain percentage of myomatous women present themselves for treatment for the relief of sterility. All displacements should be remedied by proper operations, other means having failed. When these displacements were complicated by simple hypertrophy, laceration, or erosion, amputation of the cervix at the vaginal junction should precede operation on the round ligaments. The new os should be made in such a way that there would be no exposure of the cervical mucous membrane, and the resulting scar should be as smooth as possible. Vaginal and abdominal fixation should never be practised while the woman was in the active period of sexual life. Retroposition was now and then combined with extreme lateral displacement. Here the shortened ligament must also be stretched by massage and gauze packing after the introduction of a glass plug to act as a lever. For constriction of the os internum, dilatation with steel sounds up to No. 36 French, and the wearing of a No. 32 glass plug for six days, would usually suffice. In cases of congenital ectropion of the cervix, amputation would afford an excellent chance for the occurrence of pregnancy. The sensitive hard uterus of chronic metritis offered very little prospect of a pregnancy, yet success would occasionally follow amputation of the cervix. A congenital stenosis could not be cured by dilatation.

Sterility Due to Faulty Conditions of the Tubes and Ovaries.—Dr. WILLIAM M. POLK took up this phase of the subject, and considered also the extent to which operations might be performed upon the uterine appendages for the relief of this condition. He said that it might seem strange to many to suggest an abdominal section for the relief of sterility, but it was much the same as performing cesarean section for the relief of an already existing pregnancy. The question raised was as to whether one was justified in recommending laparotomy solely for the purpose of relieving sterility. The speaker answered this question in the affirmative, brushing aside lightly the supposed danger of such a procedure. Four illustrative cases were cited. In the first the relief of sterility was a question involving domestic happiness; in another, the woman was miserable and unhappy because she was barren; while in still another the question of inheritance of property entered into the question. Operations on the appendages had been done, and had resulted in three out of the four in relief of the sterility. He knew of thirty-five cases in which operations on the appendages had cured the sterility. In women in whom there were no symptoms of pelvic disease, and operation was proposed only for the relief of the sterility, it was probable that one would find in the pelvis organized adhesions involving the ovaries and tubes, perhaps also a hydrosalpinx or some muco-pus in the tubes. The tubes should be freed from all adhesions, and the opening of the tube sealed, turned back, and fastened in this position with very fine catgut. The end of the tube should then be placed against the ovary, and held there by a stitch through the mesentery of the tube—not applied directly to the ovary and sutured there, because by so doing the chances of conception were diminished. Small cysts in the ovary should be punctured; larger ones should be excised. The round ligaments should be shortened intra-abdominally, thus curtailing the chances of subsequent formation of adhesions, and eliminating also the baneful effect of retroposition of the uterus.

Dr. BACHE EMMET said that he was thoroughly convinced of the value of the procedure advocated by Dr. Polk, it being understood, as already stated in that paper, that other recognized therapeutic procedures had been exhausted. He had been under the impression that Dr. A. Palmer Dudley's twenty-eight cases of conservative surgery on the appendages had not been previously sterile, and recorded cases of this class could now be numbered by the hundreds.

Dr. A. PALMER DUDLEY said that chronic passive congestion of the pelvic structures was the prime cause of sterility in women, whether young or old. This subject had been ably discussed in the work on ovarian tumors by the late Dr. Peaslee. Laparotomists knew very well that frequently the ovary was found glued to some portion of the broad ligament. This arrested peristalsis and interfered with the function of the tube. The latter was often found so kinked that the ovum could not reach the uterus, and was, therefore, discharged into the pelvic cavity, and died there. He agreed with Dr. Polk regarding the comparative freedom from risk at the present day of laparotomy. He was not partial to the use of Dr. Wylie's stem pessary, indeed, from its action in his own cases, he was afraid of it. In his opinion, it was much better forcibly to dilate the canal with laminaria tents under proper aseptic precautions. Dr. Dudley said that he had recently reported 205 consecutive abdominal sections without a death, in which twenty-eight children were known to have been born at full term after these operations. He was careful to cut the ovary longitudinally instead of transversely, because by the latter method the nerve supply was needlessly interfered with. He was not prepared to say positively that conception had followed surgical work of this kind done on cases of pyosalpinx, although he had the statements of two patients to the effect that pregnancy had followed even in such cases.

Causes of Sterility Occult.—Dr. HENRY C. COE said that to his mind the causes of sterility were usually much more occult than was commonly supposed. Most surgeons knew that in some cases even after the most thorough operations on the uterus and appendages, sterility had not been relieved. Because of our lack of knowledge of the true causes of sterility he thought we were apt to assume too much in regard to treatment. He had never yet found a patient who was willing to submit to a laparotomy for the cure of sterility alone in the absence of other symptoms. It was often assumed that sterility had been relieved by an operation on the appendages, and yet such an operation was rarely done alone; it was often combined with dilatation or division, correction of displacements and amputation of the cervix. The most difficult cases to diagnose were those in which the sterility was dependent upon a few fine adhesions at the end of the tubes resulting from a previous attack of gonorrhoeal salpingitis. It was time for us to go beyond the old and well known mechanical theory of sterility, and study the subject from another standpoint. We should be very careful in the matter of prognosis, for patients who were willing to submit to surgical treatment for the relief of sterility expected definite results.

Dr. H. J. BOLDT thought it was dangerous teaching to advise a patient to go about with a stem pessary in position. After such treatment, an ill-developed uterus would often appear larger, but this increase in size he would not attribute to better development of the organ but rather to inflammatory processes resulting from the irritation produced by the stem. He agreed with Dr. Ill as to the advisability of doing an amputation of the cervix for hypertrophy. Patients on whom multiple myomectomy was performed were most likely to abort if they conceived at all. While deeply interested in Dr. Polk's paper, he must confess that he had never had a patient who seemed willing to submit to such an operation for the relief of sterility alone. He was thoroughly in accord with Dr. Coe regarding the necessity for great caution in giving a prognosis in these cases, particularly when it was proposed to relieve this condition by an abdominal operation.

Dr. R. WALDO said that while listening to the discussion this evening, he had wondered why the removal of a small portion of an ovary or of a tube should relieve the sterility. Was it because the remaining portions were stimulated to increased activity? He could not understand how the removal of a diseased portion of a tube or ovary could favor impregnation, unless by so doing an obstruction was also removed. He had performed a very large number of plastic operations on both the tubes and ovaries. He had invariably slit up the tube, and stitched with fine catgut the lining membrane to the peritoneum, so that the mucous membrane was exposed. We knew very little about the site at which impregnation took place, though he believed that, in a large number of cases, it occurred in the dilated outer portion of the Fallopian tube. One of the speakers had referred to the kinks in the tubes, but it should be remembered that these tubes were always crooked, and that although quite tortuous, it did not follow that the lumen was obstructed.

The Male Often at Fault.—Dr. H. N. VINEBERG emphasized the absolute necessity of first examining the husband before treating the wife for sterility. Some authors stated that in 33 per cent. of the cases of sterility the fault was with the husband, and his own observations in dispensary practice showed this cause to be operative in about 25 per cent. of the cases. He had heard no mention made of a rather common form of sterility observed in cases in which the sexual organs were normal, *i. e.*, those in which the seminal fluid was ejected immediately after deposition by a spasm of the vagina.

Dr. WYLIE said that he did not look upon his drainage tube as exactly the same as a stem pessary, and he was positive that there was no occasion for bad results from the woman's going around with the drainage tube in place. Such treatment often caused a decided and permanent development of the uterus, and along with this it was not uncommon to observe a general improvement in the physical development and in the nervous system.

Dr. Ill said that he had been so astonished on hearing of the subject about which Dr. Polk proposed to write on this occasion that he had written to over one hundred practitioners to find out their practice, and he had found only four out of this number who said that they had suggested such a procedure to their patients as a means of relieving sterility. When one considered the abject misery of some of these women because of their sterility, it seemed very wise to propose, as Dr. Polk had done this evening, to relieve them by an operation which, at the present day, had been robbed of its terrors.

Dr. J. Riddle Goffe said that he had done these conservative operations on the appendages in about 100 cases, operating through the vagina, and he knew of eleven pregnancies having followed these operations. A positive cause of sterility was to be found in occlusion of the tubes, and hence the wisdom of adopting the plan of attacking the appendages. The safest way of doing this, in his opinion, was by operating through the vagina. Dr. Goffe said that he had operated through the vagina on two private patients for the simple indication of sterility. In both instances pathological conditions were discovered and were removed, but only one of the patients conceived following the operation.

Dr. Polk said that in this discussion he had carefully eliminated the question of diseased conditions, and had presented the categorical question, "Shall abdominal section be introduced as a cure for sterility?" When it seemed clear that the cause of the trouble lay in the appendages alone, then it was proper to submit to the patient the question of whether or not she was willing to submit to a laparotomy in the hope of being in this way cured of the sterility. In answer to the question as to how one was to determine whether or not there was sufficient disease of the appendages to warrant an abdominal section with this object in view, he would reply that it was easy and safe to make an exploratory incision through the vagina and positively settle this point. In one case in which he had amputated the tube, there was a large hydrosalpinx, and to his surprise the woman subsequently conceived

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 6, 1902.

George L. Peabody, M.D., Vice-President, in the Chair.

The Treasury Department and the Exclusion of Consumptives from This Country.—A communication was read from the United States Treasury Department in reply to the letter of inquiry sent by the Academy of Medicine. It stated that a written opinion on the matter had been prepared by the Supervising Surgeon-General of the United States Marine Hospital Service, in response to a specific request from a commissioner of immigration, in which it was stated that tuberculosis of the lungs "is a dangerous contagious disease" within the meaning of the regulations of the Department bearing on this subject.

Dr. S. A. Knopf read a number of letters endorsing the resolutions that he had introduced.

Dr. C. E. Quimby objected to the resolutions: (1) Because he thought one should not criticise the government in this way without long and careful consideration; (2) Because the present assemblage of, perhaps, fifty or sixty could hardly be taken as representative of the membership of the Academy or of the ten thousand physicians in this city; (3) Because the resolutions appeared to charge that this action of the government was founded upon ill-advised opinion and ignorance; (4) Because it was practically begging the question to say that pulmonary tuberculosis is not a dangerous contagious disease, but is a communicable disease, when every one knew that the consumptive does not directly hand the disease to another but spreads it broadcast through the land; (5) Because if tuberculosis were what we had said it was—a disease requiring the tearing off of the wall-paper and the thorough renovation of the house in which a consumptive had lived, then the disease could not be effectively checked unless the person suffering from it were made a marked individual, and was placed where he could no longer be a menace to the community, and (6) Because he thought we would stultify ourselves by adopting any such resolutions as had been offered to the Academy this evening.

Dr. William H. Thomson said that some of the most disgraceful wrangles in medical history had occurred in connection with disputes regarding the meaning of such terms as contagious and communicable. In 1855 the Massachusetts Medical Society had solemnly declared that efforts should not be made to control and quarantine cases of cholera because this disease was not contagious, but one dependent upon a miasm. Dr. Thomson said he was very much in favor of adopting the resolutions presented, because it was unnecessary, cruel and tyrannical to label persons with a name which the masses understood to mean was synonymous with dangerous contagion.

Dr. C. L. Dana said that he thought that the chief objection to taking action this evening was the fact already alluded to by Dr. Quimby, *i. e.* that although this Academy had a membership of eight hundred or more there were only fifty or sixty present. Although these resolutions had been under nominal consideration for a month, they had not been referred to a committee, and did not, therefore, come before the Academy at this time with a proper official endorsement. Dr. Dana then moved that these resolutions be referred to a committee of five, to report back to the Academy of Medicine in one month.

Dr. Alfred Meyer called attention to the fact that the special rules of the Academy with regard to action on such subjects had been complied with in every respect. Moreover, he saw no reasons why physicians should not be outspoken upon a subject about which they had a right to feel themselves well informed, even though certain governmental medical officers had seen fit to express an official opinion on the same subject a little earlier.

Dr. Andrew H. Smith said that as every member of the Academy had received notice that these resolutions were to come up for action at this time it was their own fault if they did not come this evening and voice their opinions.

The motion to refer to a committee was lost, and then the resolutions introduced by Dr. Knopf were adopted in the following form:

Whereas, The Treasury Department of the United States, upon recommendation of the Surgeon-General of the Marine Hospital Service, has recently decided to classify pulmonary tuberculosis with dangerous contagious diseases, be it

Resolved, That the New York Academy of Medicine deeply deplores this decision, which is not based either on clinical experience or on scientific experiments.

Resolved, That the Academy considers the exclusion of non-pauper tuberculous immigrants and consumptive aliens visiting our shores unwise, inhumane, and contrary to the dictates of justice.

Be it further Resolved, That, while the Academy upholds the fact of the communicability of tuberculosis and urges all possible precautions against the spread of the disease, occasioned by tuberculous sputum or food, the Academy is opposed to all measures by which addi-

[illegible]

Blackwell's Island as a Site for a Tuberculosis Hospital.—The [illegible] consisting of Drs. H. P. L[illegible] [illegible] presented a report in which they recommended [illegible] Island for the [illegible] of consumption, and expressed the opinion [illegible] of the Department's [illegible] it would be [illegible] to make any needed alterations. The committee also [illegible] that they did not wish it understood that this report was a final decision of the matter. The report was adopted and a copy of the report was ordered sent to the Commissioner of [illegible]

The Phenomenon of Inhibition and Its Possibilities in Pathology, Especially in Its Relations to the Diseases of Myxœdema and Exophthalmic Goiter.—Dr. S. J. Meltzer presented a paper with this title, but for lack of time, [illegible] portions of the article. Speaking of the well-known inhibitory action of the vagus nerve, the author said that stimulation of the peripheral end of this nerve caused (1) Diminution of the number of heart beats, (2) Diminution in the force of the contractions, (3) Diminished tonus of the cardiac muscle, (4) Diminished excitability of the heart muscle, (5) Abolition of the conductivity of the heart muscle, and (6) A reversal of the direction of the current in the heart muscle. There could be no doubt about the omnipresence of the phenomenon of inhibition throughout the body. Rest was a sort of temporary death without any stimulation or any inhibition. The difference between activity and rest was that in the former state excitation was prominent, whereas in the latter inhibition prevailed. The potential energy of the muscles, nerves and nerve fibers were probably of a different kind, yet the nature of the irritability remained the same in all these cases. The inhibitory fibers became exhausted more quickly than the accelerator fibers, hence when both were stimulated at the same time, on the cessation of the stimulation the accelerating action would become manifest. The importance of inhibition to the regulation of animal life was obvious. If the vascular system were controlled by the structures alone there might result extreme anemia, and even necrosis of the tissues from excessive inhibition under certain circumstances. Many years ago he had suggested that, in groups of muscles, such as the flexors and extensors, when one set was stimulated to contract, the antagonizing muscles were inhibited. This arrangement had been found to be actually present in connection with the function of [illegible]. This form of inhibition was certainly a [illegible] mechanism in the economy.

The Secretion of Bile.—The discharge of bile occurs about one hour after a meal, but what was it that caused the [illegible] from the [illegible] of the time? Stimulation of the [illegible] end of the [illegible] nerve caused contraction of the gall-bladder and relaxation of the [illegible] muscular fibers—in other words, this nerve contained motor fibers for the gall-bladder and inhibitory fibers for the gall-duct. The entrance of the food into the duodenum was what excited the activity of this mechanism. A disturbance in this reflex mechanism would be followed by all the [illegible] which we knew [illegible] obstruction of the bile passages. He was of the opinion that many cases, diagnosticated as catarrhal jaundice, were in reality instances of such nervous disturbance of the mechanism governing the flow of the bile. The [illegible] of gastric catarrh and [illegible] was by no means proof that the case was one of catarrhal icterus. The failure of the bile to reach the duodenum might just as well be the result of a failure of the nervous mechanism as of the presence of a catarrh of the bile duct. He did not, however, wish to be understood as claiming that catarrhal jaundice does not occur. On the [illegible], [illegible] when two parts of the [illegible] not far apart contract simultaneously, there [illegible] of the [illegible] and [illegible]. It was probable that [illegible] the sphincter of the gall-bladder and the [illegible] simultaneously.

Family Periodic Paralysis.—[illegible] was made to [illegible] family periodic paralysis—a form of paralysis in which one of the most characteristic features was the total absence of [illegible] irritability of the muscles to mechanical or electric stimulation. The muscles behaved like the heart muscle when under strong vagus stimulation. [illegible] muscles respond to stimulation. It had been found that potassium [illegible] phosphate would abolish the excitability of a muscle, and that this excitability could be restored by washing out the phosphates with [illegible]. In these cases of paralysis it had been found that [illegible] after the attack of paralysis the urine contained three times as much phosphate as before the paralysis, and that during the attack the quantity of phosphates was about normal. Hence, it was reasonable to suppose that this form of paralysis was the result of an over-production of the phosphates.

Myxœdema and Graves' Disease.—In myxœdema the heart beats were small and the movements of the bowels were retarded, muscular contractions were slow, the body temperature was lower than normal. The absence of facial expression was dependent upon a lack of tonicity in the facial muscles. In this disease there was most probably a greater or less deviation in favor of inhibition in the muscles of the body. In Graves' disease the deviation was more in the direction of excitation. The presence of the disease of the *tâche cérébrale* and the great tendency to blushing would seem to point to a special tendency of the great vascular area controlled by the splanchnic nerve to undergo contraction. Dr. Meltzer, in closing, said that the object of this study of inhibition and excitation was to learn more of the influence which certain substances have over these important functions in the body. A hint of what might be learned in this field was afforded by the remarks made about paralysis and the over-production of the phosphates.

Dr. C. L. Dana said that so many facts regarding inhibition had been established that it was time to apply this knowledge, and it could hardly be better done than in the admirable paper just presented. It was certainly true that it had been demonstrated that by irritating certain parts of the brain cortex of the monkey an inhibition of one group of muscles could be produced and an excitation of another, but we had not yet found any center by which we could produce inhibition without causing a contraction. Sherrington had succeeded in inhibiting the action of one of the muscles of the eye, the internal rectus, after having cut the external rectus, and to that extent he had found a sort of inhibitory center for that muscle, but such centers had not been found generally. The theory propounded regarding periodic paralysis was a most fascinating one, but [illegible] remained yet to be demonstrated. The momentary paralyses of one arm or one leg [illegible] observed in neurasthenic and hysterical persons might perhaps be explained by a sudden inhibitory influence. The doctrine of inhibition had even been applied to the phenomena of epilepsy, and with apparent good reason. One of the most puzzling phenomena to him in regard to Graves' disease was the vascular changes in the skin, but this had been clearly explained in the paper.

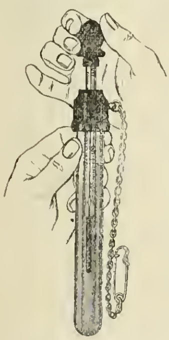
Dr. William H. Thomson said that he had long felt that the familiar inhibitory phenomena connected with the vagus were only a type of many similar phenomena throughout the whole nervous system. He was of the opinion that almost every nerve function was more or less inhibited or controlled by others, and that this applied even to the higher mental processes. Dreams appeared to him to be mental processes devoid of inhibition, and it was chiefly in this respect that they differed from ordinary systematized thought. He had no hesitation in accepting the view advanced by the author, that most of the symptoms of Graves' disease were illustrative of a weakening of the controlling power—a paralysis of inhibition; an uncontrolled excitation. However, he could not agree with him that myxœdema was due to an increase of inhibition and a decrease of excitation. In myxœdema we found the tissues surcharged with a mucoid fluid, which acted upon the muscular and nerve functions very much as ashes do in the banking of the fires of a steam engine. His idea of myxœdema was that all of the vital functions were being slowly extinguished.

Dr. **Meltzer** said that where there was life, inhibition was always present, and we knew now that it was impossible to find centers of inhibition—indeed, this very fact was proof of the omnipresence of inhibitory processes in the body.

New Instruments.

AN ASEPTIC CLINICAL THERMOMETER.

The clinical thermometer is used, perhaps, more constantly and in a greater variety of diseases than any other article of the physician's outfit. The necessity of sterilizing such instruments before use must be recognized, when we reflect that the temperature is most frequently taken in the mouth, which is the abiding place of innumerable germs, and which furnishes a favorable medium for the propagation of bacteria. That the bacterial flora found in the oral cavity can be transmitted by clinical thermometers has been shown by repeated bacteriological examination. The rule of absolute chemical cleanliness should, therefore, be as rigidly observed in the use of clinical thermometers as with instruments used in operations.



The futility of the customary washing of the thermometer in water and then wiping it upon a towel or handkerchief is now generally recognized. Many practitioners attempt to limit the danger of infection by carrying in their thermometer cases a pledget of cotton moistened with an antiseptic solution. This method is found unreliable, since examination of thermometers so carried reveals the presence of bacteria. To be properly sterilized, the instrument must be immersed in the antiseptic solution for a sufficient length of time. The custom adopted by hospitals of keeping thermometers in a disinfecting solution is effective, but is not adapted to the needs of the general practitioner.

To meet the requirements of a practical pocket sterilizer for thermometers, the antiseptic thermometer case, herewith illustrated, has been devised. This consists of a heavy annealed glass tube for holding the antiseptic solution; a rubber diaphragm resting upon the mouth of this tube and making a water-tight closure; a hard rubber neck-band for retaining the diaphragm in position; a hard rubber screw-cap, to which is attached the thermometer, and a safety chain for fastening the whole securely to the clothing. In using this appliance, the glass tube is nearly filled with an antiseptic solution, such as corrosive sublimate 1-500. The neck-band, with diaphragm, is then replaced, and the thermometer inserted through the perforation in the diaphragm. This may then be safely carried in the pocket, since the toughness of the glass insures it against breakage, and the diaphragm prevents leakage.

To remove the thermometer from the case it is only necessary to unscrew the cap, as shown in the cut. On withdrawal of the thermometer, the diaphragm completely closes, so that the solution cannot run out, even though the case be inverted. The thermometer is returned to the case with equal ease. This case is commendable because it is simple in construction and operation; is convenient in size; will not leak, and the thermometer is effectively sterilized, since it is always immersed in the antiseptic solution when not in active use. These cases are made by the Norwich Pharmacal Co.

THE AUTOMATIC LIGATURE PASSER.

By E. Pierre Mallett, M.D.,

New York.

This instrument, a description of which was published several years ago in this journal, has since undergone such an important modification, and has proved itself of such value to me in all abdominal and vaginal work where it is necessary to pass ligatures, that I think it worthy of another presentation. The modification consists in having a strong spring in the handle, which throws open the blades, thus putting the ligature through itself and making its action as nearly automatic as possible. While the accompanying cut shows its action very clearly, a word or two of description may not be out of place. The upper, or needle blade is made like a pedicle needle, except that it has an open or self-threading eye. The lower blade is blunt and smooth and acts as a counter pressure to the needle. In the end of this lower blade is a small slot, just large enough to admit the needle, while across this slot is a groove, which receives and retains the ligature until picked up by the needle. The modus operandi is simplicity itself. A ligature of the desired size is firmly placed in the groove of the lower blade. This blade, the one containing the ligature, is then introduced behind the pedicle, or structure to be ligated, being guided by the fingers of the left hand, which is grasping the pedicle, while the needle blade is passing at the same time over the upper surface of the pedicle under the guidance of the eye. When the particular spot is reached where it is desired to pass the ligature, the handles are firmly compressed and the instrument does the rest. That is, the needle blade is forced

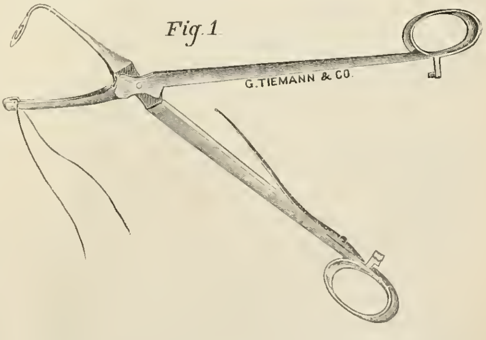


Fig. 1

through the pedicle tissues is pulled up [illegible] the ligature about the groove in the lower blade by means of the open eye. At this point the spring of the handle forces the needle back through the pedicle, taking the ligature with it. The instrument is then withdrawn and the ligature is in place.

The advantages this instrument would seem to possess over those in use at the present time for similar purposes are:

First.—The same instrument with [illegible] ligatures can be passed through the tissues, particularly those situated deeply in the pelvis.

Second.—The operator is enabled to pass the ligature quickly with one hand, while the other hand is engaged in maintaining the structures in correct position.

Third.—The operator is not dependent upon the skill or dexterity of an assistant in either catching the ligature when it has been passed through the tissues by the pedicle needle or in placing the ligature properly within the groove of the Cleveland passer if this instrument be used.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 15, 1902:

	Cases	Deaths
Measles	[illegible]	[illegible]
Diphtheria and croup	[illegible]	[illegible]
Scarlet fever	[illegible]	41
Smallpox	58	14
Varicella	[illegible]	
Tuberculosis	[illegible]	166
Typhoid fever	[illegible]	8
Cerebrospinal meningitis	..	8

Population of the United States.—The total population of the United States on June 1, 1900, was 76,303,387. Of native-born persons there were 65,843,302, and of foreign born 10,460,085—that is, of every 1,000 persons in 1900, 863 were born in the United States, and only 137 outside the borders of the country. If in the foreign element are included the children of foreign white parents the foreign element now constitutes about one-third of the total population—34 per cent.

The native whites of native parentage constitute slightly more than one-half—53.8 per cent.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine-Hospital Service, during the week ended February 14, 1902:

SOME VARIETIES, COMPLICATIONS, AND SEQUELÆ OF SMALLPOX AS NOTED IN THE NORFOLK EPIDEMIC OF 1898–99.

By LEMUEL C. SHEPHERD, M.D.,
NORFOLK, VA.

It is not my intention to write an exhaustive paper on variola, but only to record some clinical facts noted by us while personally caring for and treating nearly a thousand cases during our recent epidemic.

In describing these varieties of smallpox, I wish emphatically to enforce the view that all these various forms are merely modifications of one and the same disease, and that variola, in all forms, is an entirely separate and distinct disease from varicella, so great an authority as Professor Kaposi of Vienna to the contrary notwithstanding. I was rather surprised, some years ago, to hear him assert in all seriousness at his clinic, while showing the class a case of chickenpox, that it and smallpox were one and the same disease.

In classifying these varieties of smallpox, I found many cases in which the form was not sharply defined, and it was hard to decide to which class the particular case belonged. In addition to the three typical varieties, varioloid, discrete, and confluent variola, we found many cases coming between these and having distinctive features of both its preceding and succeeding variety; however, they all have the same general outline.

I would emphasize the fact that malignant cases may be contracted from the lightest, and will point this out incidentally as I go along with the report of cases.

Varioloid, or benign variola, may be divided into several forms: In the abortive form the pocks fail to pass through the later stages of their development, stopping short at the papular stage, or if reaching the vesicular stage, drying up and shriveling on the fifth or sixth day of the eruption. In other instances the eruption passes rapidly and imperfectly through all phases of its development, producing more or less dwarfed forms of the pustules. In still other instances, the eruption is perfect in its development, passing through each stage naturally, but is extremely discrete.

The following cases are descriptive of these varieties:

Case I.—H. T., colored female, aged fifteen years, successfully vaccinated about eight years previously, was brought in, March 24, 1899, with modified case; eruptions plentiful, but superficial. She gave a history of few or no premonitory symptoms, disclaiming chill, but admitting some aching, which was general, and not confined to head and back; this eruption had appeared only two days previously. The lesions were discrete, but plentiful, with no areola or swollen base surrounding. They did not grow and mature, but, instead, followed much the usual course of varicella. They began to dry in two days after entrance, and in about a week were scabbed off and clean, leaving only a few dark spots over the face and hands, surfaces exposed to light. Ten days after entrance it would have been hard to tell, except for these spots, that the girl had ever had an eruption. Just twenty-one days after she was brought in, we found in the same house an old woman and a child with well-pronounced cases of smallpox; they had already reached the fourth day of the eruption, so that their incubation period corresponded with our average. The old woman was an invalid, and was confined to one room, and the baby was left with her, and the young girl with abortive smallpox waited upon them the same day she was carried to pest-house.

Case II.—M. F. S., colored male, thirty-five years old, large and well developed, vaccinated some years previously; found April 6, 1899, with a most discrete eruption, not more than two or three papules on the face, and half a dozen over the chest and shoulders; the papules were small and dry and superficial, resembling acne, not swollen at base; he said there was no itching. The eruption over the forearms and wrists, though very slight in extent, seemed somewhat in advance of the rest, and there were beginning crusts, giving each the appearance of having a little plug in its center. He disclaimed previous headache or backache, chill, fever, or nausea, though some of these symptoms had probably been present to a slight degree. The eruption dried three or four days after entrance, scabbing off, and leaving practically no scar. The patient's wife, recognizing the inspectors when they first found her husband, escaped through the back door of their house. The inspectors were not able to locate her until she became ill herself, when she was compelled to return to her own home, her relatives fearing to harbor her longer since they suspected the nature of her disease.

The house having been watched, she was found immediately upon her return, and was brought in, just eighteen days after her husband, with a discrete though well-marked case.

Case III.—Henry A., colored, aged thirty years. He thought he had never been vaccinated, and there was no scar to indicate successful vaccination. He was sent to the pest-house November 1, 1898, with an abundant papular eruption over face, hands, and entire body; had been exposed to contagion and had had prodromal symptoms after the usual incubation period. Two other persons were carried from the same house one and two days before, respectively, and one of these presented a well-marked confluent case. All of these had been exposed to a confluent case that had been carried out about eighteen days previously. This patient stated that he had spent the night with the other three when the eruption first appeared upon himself, about two days before being carried to the pest-house. In the case of Henry A. the eruption was vesicular, and did not advance beyond this stage; the vesicles did not grow larger and become filled with pus, but instead they dried rapidly and small scabs formed; there was no secondary fever, and the eruption aborted. The eruption was so abundant, in this case, that had the vesicles grown and become pustules, they would of necessarily have run together, and the disease have become confluent.

Case IV.—Peter H., colored, aged thirty-five years, [illegible] and was quite sure he had never been vaccinated, was brought in March 29, 1899, with an abundant vesicular eruption, which was general. He had been quite ill with chill, fever, headache, and backache before the eruption appeared. He had no secondary fever, and vesicles dried without becoming pustular.

Case V.—J. H., aged thirty-three years, white, was brought in May 11, 1899, with a rather mild case. It was peculiar that while the eruption was normal in regard to the time of its appearance and passed through the various stages of its development, finally becoming pustular, still the pustules were dwarfed and not well filled, and they scabbed over quickly.

During the epidemic we noted a large number of cases with histories similar to this one. Usually the patients had been previously vaccinated; many cases occurred in persons who had been vaccinated within three months with seeming success. The vaccinations had modified the disease but did not protect. We adopted a stronger virus—at least, a more reliable variety.

In the next two cases which I report the eruption was perfect in its development, but extremely discrete.

Case VI.—W. F. A., aged thirty-two years, white, came in, March 12, 1899, with a mild case that was already well advanced; the vesicles were large, having well-marked areolæ, and well filled; they became pustular, and some were umbilicated. Each stage followed the previous one naturally, and finally the case being fully developed without being cut short in any way. However, there were not more than a dozen pustules over the entire body.

Case VII.—Robt. S., aged forty years, white, was a blacksmith. We found him at work in his shop on January 27, 1899. He had a most discrete eruption; three or four large indurated papules about face and head, several over body, and one or two in palms of hands. When I told him that it would be necessary for him to go to the pest-house, he objected loudly. He said that he had never felt better in his life; he had his forge blowing and the iron hot; he had work to do, and he felt like doing it. He assured me that he had not left his shop for more than two weeks, being engaged in his work all day and eating and sleeping in same building alone. He thought it was impossible for him to have been exposed to smallpox. After reaching the pest-house, the patient admitted having had a chill with some general aching three days before. I found the eruption to be perfect in its development, passing through each stage naturally. On February 11, while making rounds in his ward, this man came to me privately with a most pitiful tale. He had received a note from a friend outside telling him of a poor widow with two children who bore the same name as himself, which fact he seemed to think quite a coincidence. He said the note told that there was nothing to eat in the house, no fire, and it was quite certain the mother had smallpox. We were in the midst of a blizzard with about two feet of snow; so, the elements being so much against the woman, he was forced to own that he had visited her house the night before we sent him to the pest-house, and she had fingered the bumps and rubbed his head. The woman had a discrete, but well-marked case.

Discrete variola has, probably, longer incubation and invasion periods than has the confluent variety. Many of us who had to deal with smallpox during the epidemic noted the incubation period as being rather longer than that set down in the books.

The greater number of cases were brought in eighteen days after known exposure, and so, allowing three days for prodromal symptoms, it made the incubation period about fifteen days.

I now report a typical discrete case and then a confluent one. I had not intended to report cases of these, the ordinary varieties, but I find that there still exists doubt in the minds of some members of the profession in various parts of the country to which this epidemic has now spread, as to its true nature.

I want to emphasize the fact that while many of the cases occurring are mild, still the disease is real smallpox. Therefore, in addition to the atypical cases which I had intended to report only, I will mention briefly the histories of two typical cases which I copy from my case book, and it can be seen how nearly they resemble cases that occurred ann were described fifty or a hundred years ago.

Case VIII.—Arthur D., aged twenty-five years, white, was seen first February 23, 1899. He had no eruption at the time, but complained of headache, backache, and nausea; had temperature of 103.6° F. after a chill. I had been sent for to see his bedfellow, who was developing a confluent case, and had two days start of him, and was already beginning in papular stage, though it is probable they had both been exposed at same time. Eruption had appeared on second man by next day, and his temperature had fallen to a little above normal. The rash appeared first on forehead, neck, and face, and about the wrists, then gradually spread to the extremities. These little macules of the first day had become papular by the second day, and gave the shot-like feel; vesicles had formed on the fourth day, and were large and well filled, becoming pustular about the sixth or seventh day.

At this time the patient complained of much pain and burning of hands and feet. The pustules were quite thick over entire surface, but they did not become confluent. The integument was much swollen, and there was a distinct areola around each pustule. On the seventh day many of the pustules were umbilicated; in two or three days more desiccation began, and desquamation followed in regular order. There was no complication, and patient was discharged March 19, without pitting.

Case IX.—*Confluent.*—J. B. E., aged forty-three years, white, never successfully vaccinated, came in, March 1, with plentiful fine papular eruption, having had severe prodromal symptoms. This patient was in a rather bad physical condition; he had phthisis and was overworked and run down. There was much redness and œdema of integument, even in papular stage, and with beginning pustular stage, about seventh day, the eruption had become confluent over entire body as well as face. Later, when the pustules began to rupture, the entire surface was bathed in a thick yellowish pus, giving that most pronounced odor, which is characteristic of bad cases of smallpox. This viscid pus dried down into thick black crusts; his eyes were entirely closed by them, and his nose and other air passages were so blocked by them that the patient seemed dying of suffocation. He was unconscious for more than three weeks, and wildly delirious for about one week. On one occasion he knocked his nurse down with his fist, and on another he escaped and ran across an adjoining field, a distance of half a mile, before he could be captured and brought back.

When the black crusts had dried and come away, other scales formed and peeled off in successive layers—desquamation extending over several weeks.

This patient was left much pitted, and with almost total absence of hair, beard, and eyebrows. He had a long and tedious convalescence, for, after desquamation was fairly under way, and for several days, he had seemed much better, then his lungs began to give him trouble. His temperature again ran up, cough increased, and he expectorated, each day, large quantities of a green-looking pus, with a gangrenous odor. He developed an enormous appetite at this time, took and assimilated large quantities of food. For two weeks he had each day three quarts of milk, besides buttermilk, eight eggs, and two large bowls of soup, and this, in addition to the "ordinary plain diet" given to other convalescents. He gained flesh rapidly, and two months afterwards he weighed thirty pounds more than when he contracted smallpox.

During the epidemic we treated about sixty confluent cases, and with at least twenty-five the eruption was equally bad as with the case just mentioned. In addition to these we had a much larger number of what might be called semiconfluent; the eruption was confluent over face, but only partly so over body and extremities.

We noted two or three cases of a rather peculiar variety that I find put down as "corymbose," the pustules were confluent in patches or clusters, and the patches were separated from each other by intervals of unaffected skin. This was especially well shown in one case, and since it was complicated with epilepsy, I will mention its history.

Mary J., aged twenty-five years, colored, was sent in, May 6, in the papular stage. In due time the rash became confluent over face and in some parts of her body—over the lower part of abdomen, inner side of thighs, and in the popliteal spaces the eruption was arranged in clusters. There would be seen an irregular space of integument as large as a hand, thickly studded with the fine eruption; these clusters varied somewhat in size and shape, and the integument between clusters was either entirely free of the eruption, or it was extremely discrete. Patient began having convulsions about fourth day of the eruption, and while she was ill with the disease, she had from three to twelve each day; when eruption was better she had them at longer intervals. She was an epileptic, and the disease, smallpox, seemed to increase and aggravate the attacks. The corymbose variety is spoken of as being rare and extremely fatal.

We noted some cases in which the eruption took a peculiar course toward the end of its development. It ran a natural course until it began to scab, when the pustules on the face and other exposed parts became surrounded by red and very much indurated bases, the solid parts of the pocks remained, and were much raised above the surface of the integument; continuing to grow they formed papular excrescences resembling warts. These little growths were hard to reduce. I noticed the condition with two white cases, and with three or four colored men, to a lesser degree; these latter were mulattoes. I think the eruption due to the condition of the skin, and it seems to me the patients were all of a tubercular diathesis.

In regard to complications and sequelæ, probably the most frequent were eye affections. Conjunctivitis was present in about 10 per cent. of the cases. With the confluent cases there was a high grade of inflammation with a plentiful discharge of pus. With the greater number of cases there were localized spots of inflammation, which were evidently due to the formation of pustules on the conjunctiva. The inflammation subsided promptly in all these cases, and as far as we were able to follow up the cases (both the assistant health officer and myself making an effort to watch anything of interest), no bad results have followed. We had two cases of inflammation of the cornea, but these came later in the disease; they followed very bad confluent cases in both instances. With one, a colored woman, the keratitis developed during the stage of desquamation, the inflammation was of a high grade, and an ulcer quickly formed. When the patient was discharged about three weeks later, the eye seemed better, but, upon searching her up later we found that the ulcer had left considerable opacity of the cornea, and vision was somewhat impaired. The other patient, a white man, in whom the ulcer developed about two weeks after he was well of smallpox, had a better result; the ulcer healed, leaving only a slight opaque spot and no impairment of sight.

A noticeable feature with several cases was a marked ptyalism, beginning with vesicular stage and running to late scabbing stage. One white man, with a confluent case, expectorated no less than from two to three pints each day of a viscid, tenacious fluid.

Several cases were complicated with enlarged submaxillary and sublingual glands, coming on mostly in the scabbing stage. In the cases of two negro men these glands seemed to join together and form large abscesses; after freely opening and draining them they gave no further trouble. Several others were complicated with boils or superficial abscesses, the convalescence of some were much prolonged by the presence of these furuncular crops.

A peculiar lesion developed in several cases after the eruption was almost completed. It showed especially well in the case of a negro man after a rather bad, discrete case.

The pustules, instead of drying up and scabbing on the eleventh day began to spread peripherally, so that in a day or two many of the cutaneous lesions consisted of three well-defined parts, namely, a central scab, a surrounding vesicular ring or bleb, which became pustular, and a swollen areola surrounding the pustular ring. Some of these rings measured nearly an inch in diameter. The cause of this secondary eruption seems to be infection by various pyogenic germs; this eruption was present upon the forearms, particularly in cases noted by us. It greatly prolongs convalescence.

Most of the bad cases were complicated with pharyngitis or laryngitis, or both, during the vesicular or early pustular stage, probably due to the presence of the rash in these localities.

Two infants died of either capillary bronchitis or lobular pneumonia complicating confluent cases, one aged five months, and the other only twenty-four days old. With both the lung affection came on in the desquamative stage and after the little patients had seemed much better for two days.

We had three cases complicated with labor, besides two cases of abortion. These patients all made good recoveries, though with one case the labor was abnormal, a transverse presentation, so that podalic version became necessary. We could not be certain of the presence of the rash upon the fœtus, since decomposition was already far advanced.

One case was complicated with dysentery, coming on about fifth or sixth day of the eruption, the amount of blood lost being large.

A case was complicated with typhoid fever, the typhoid symptoms not developing until late in the desquamative stage.

Cancer of breast complicated one case, and the cancer grew rapidly while she was passing through smallpox. The woman said the growth had increased more that one month than it had altogether in the previous three months.

With one case, that of a colored boy, the pig-

[illegible] unnoticed. The eruption had been discrete but very tardy, slow in developing, taking two or three days to come out after some papules had been present over forehead. It ran a normal course after this, but after desquamation was completed there were left pearly-white spots instead of the black ones which ordinarily follow this eruption in the colored race.

We had two cases in which the disease occurred the second time with the same individual, a negro woman about sixty and a negro man about forty years of age. Both claimed to have had it in childhood, and showed much pitting in evidence. They both had well-marked, though discrete, cases the second time.

FOLLICULAR TONSILLITIS *

By ROBERT CURTIS BROWN
MILWAUKEE, WIS.
ATTENDING PHYSICIAN TO THE MILWAUKEE CHILDREN'S HOSPITAL.

FOLLICULAR TONSILLITIS is a disease characterized by an exudation of a whitish or yellowish substance from the crypts of the tonsil.

The tonsils are two glandular organs, situated one on each side of the fauces between the anterior and posterior pillars of the soft palate. They consist essentially of a reduplication, more or less extensive, of the oral mucous membrane in which are enclosed an abundant deposit of adenoid elements, the whole organ having an identity and special function of its own.

The inner surface of the gland presents ten to fifteen orifices leading into small recesses, from which follicles branch out into the interior of the gland.

In its minute anatomy the tonsil resembles the other adenoid structures. It, in common with the rest of the oral mucous membrane, is invested with a thick covering of pavement epithelium, resting upon a single layer of columnar epithelium. Below the epithelium is a delicate endothelioid basement membrane, under this a mucosa formed of interlacing bands of connective tissue. This, in a normal tonsil, is so delicate as to be hardly recognizable, but in chronic disease may become enormously hypertrophied. Bands of connective tissue extend into the substance of the gland, the whole forming a framework for the adenoid tissue, or proper substance of the gland. This adenoid tissue contains an immense number of lymph corpuscles, which I consider of the utmost importance to the function of the gland.

The function of the tonsil has long been a matter of dispute. Some authorities contend that it is a secreting gland; others that it is an absorbing one. Fox and Swain evidently think that it was placed at the mouth of the fauces for the express purpose of absorbing into the system the germs of infectious disease; Stöhr and Killian believe its function is to destroy deleterious germs.

The secretion of a substance is admitted by all. Under the stimulus of inflammation an exudation is expressed from the mouths of the crypts. This exudation is a hypersecretion of the tonsil itself, reinforced by the products of inflammation, which are serum, fibrin, and pus. The crypts are normally, more or less, filled with a yellowish substance consisting of fat molecules, pavement epithelium, and lymph corpuscles. This substance is greatly increased in tonsillitis. The exudation has no texture, and is not adherent to the tonsil.

I believe that one of the functions of the tonsil is to resist infection, and that this function is probably an acquired one. That nature has provided the body with a system of defence at the entrance of the respiratory tract against the invasion of germs seems hardly to be doubted. The peculiar anatomy of the nose with its immense amount of mucus-producing surface, and the ring of lymphoid tissue around the pharynx, are provisions of nature, evidently not without a purpose.

The tonsil is composed of this same lymphoid tissue. Its peculiar situation is also worthy of notice. Anterior to the tonsil the mucous membrane has great resisting power. Septic infection of the mouth, considering the frequency of injury, is very rare. Dentists would hardly be able to do much work if the secretions of the mouth were not antagonistic to the development of toxins.

In its possession of a structure capable of producing a large amount of lymph corpuscles, the tonsil is analogous to the spleen, the thyroid gland, the suprarenal capsule, and the lymph nodes themselves. I will endeavor to show that the tonsil is probably allied to those glands in function.

The tonsil might be considered really a lymph gland, partly outside the body, its cells having acquired a special function, due to their situation and the work placed upon them. Evidence of cells becoming specialized for defensive action we see everywhere in nature. The wild pear tree has thorns for its protection, which become branches when the tree is cultivated. The berries of the holly are nestled among the leaves, some of the gemmules of which have become specialized along the border of the leaf to form spines. These spines are evidently produced to resist the onslaughts of birds, who would devour the seeds of future trees.

Killian has shown that man and domestic animals who are exposed to pathogenic germs have relatively large pharyngeal tonsils, but that in animals whose noses are long and complicated the adenoid tissue is absent.

The function of cells in plants can be readily observed. In the drosera, the plant Darwin made such a minute study of, there are cells that can be compared to the lymph corpuscles in man. As evidence that these cells in the drosera do secrete a fluid that is distinctly antagonistic to bacteria, I shall quote an experiment of that most distinguished observer of nature, Charles Darwin:

> "During very warm weather I placed together two equalized bits of raw meat, one on the leaf of the drosera, and the other surrounded by wet moss. They were thus left for forty-eight hours, and then examined. The bit on the moss swarmed with infusoria, and was so much decayed that the transverse striæ of the muscular fibers could no longer be distinguished; while that on the bit of leaf, which was bathed in the secretion, was free from infusoria, and its striæ were perfectly distinct in the central and undissolved portion."

If this humble plant, which nature has furnished with cells specialized to assimilate animal matter, is protected from microorganisms in this manner, surely we should almost expect to find such cells in the human body.

The defensive secretions with which nature has provided some animals, such as the serpents, are exceedingly poisonous. The medicinal products which we derive from plants are probably toxins of their lymph cells, which were intended by nature for their defense. It is but necessary to call your attention to the systemic action in the human body of the thyroid extract, nuclein, etc., to prove that glands containing lymph structures in animals do produce a substance resembling a toxin in action.

The function of the tonsil may be excited by exposure to wet and cold, a chill of the surface of the

---

*Read before the Milwaukee Medical Society body causing local hyperæmia and vascular engorgement. This cause would account for the predisposition of some people to the disease. Whether this form of tonsillitis is contagious, and if so, whether from the presence of some microorganism or from the toxin produced from the tonsillitis itself, requires further investigation.

When I first wrote this paper I overlooked any cause but that of an infectious nature, so much was I interested in that form of tonsillitis. But a follicular tonsillitis may be caused by any irritation, such as the inhalation of obnoxious smoke and gases or fluids, though even in these cases I think the cooperation of some germ is necessary.

The most common cause, however, is the presence of some pathogenic germ.

While in most diseases a definite microorganism has been found as a causal factor, in follicular tonsillitis the bacteriological results have proved varied. Among the organisms found are the streptococcus, the Loefler bacillus, the pneumococci, etc., besides other microorganisms that reside normally in the mouth. I believe that any of these organisms and many others are capable of causing a follicular tonsillitis. The symptoms of exudation are caused by the function of the tonsil being excited by the infection, no matter what particular germ endeavors to gain a foothold and develop its toxin.

I would call your attention to the frequency with which tonsillitis complicates almost all the infectious diseases, notably scarlet fever, measles, epidemic influenza, etc. Its relation to diphtheria I wish to discuss more fully. It also complicates rheumatism, but to that disease it bears another relation.

From the symptoms of a disease we can often ascertain the probable point of infection and the methods by which the poison is being eliminated. In measles and epidemic influenza, by the catarrhal symptoms; in scarlet fever and diphtheria, by the sore throat; in typhoid fever, by the diarrhœa.

Here I wish to call your attention to the analogy of the tonsil to Peyer's gland, which it greatly resembles in structure. In malaria we have a direct infection into the blood by the mosquito bite, which also conveys the poison of yellow fever. Bubonic plague has a tonsillar form, but the main source of infection is by the bite of the flea.

The involvement of the spleen in many infectious diseases shows that it bears some relation to the elimination of their various poisons.

I wish to note the fact that in those diseases in which the infection is directly into the blood, or through the intestinal canal, the spleen is more liable to be affected than in those diseases which gain entrance to the respiratory tract; for example, malaria and typhoid fever.

The varied rash of, for instance, scarlet fever, measles, and smallpox is evidence that the toxins of these diseases are essentially different, and that the skin is assisting in their elimination.

If the anatomy and function of each tissue, and the relation each specialized cell or gemmule bears to a supposed toxin that is either the natural waste product of the body itself or some deleterious matter that has gained entrance from the outside, are held clearly in one's mind, a great flood of light is thrown upon the etiology of disease.

The skin may become diseased in eliminating waste products by, for instance, urticaria. The inner walls of the blood vessels may become hardened by the continued presence in the blood of the poison of alcohol or syphilis, causing endarteritis. The endarteritis of old age may likewise be due to the long-continued resistance of cells to the body's natural waste products that the blood is carrying to some excretory organ.

In the Medical Record of December 14, 1901, there is a valuable epitome of the subject of rheumatism as a cause and effect in inflammation of the throat. I will quote from it:

"Fowler has published twenty cases of acute rheumatism ushered in by acute tonsillitis. Lenox Brown says the rheumatic diathesis is always present in these cases of relapsing acute tonsillitis. Wagner finds the same germ in rheumatic affections, in the tonsils, joints, and other parts of the body, and holds that the angina is the first manifestation in most of the cases. Graedel says the tonsil is the local point of infection from which the cocci or germs invade the other parts of the body.

"In a recent article by St. Clair Thompson on 'Rheumatic Fever in Throat Affections' occurs the following: 'In his Milroy lectures Newsholme expresses his views that it is probable in rheumatic fever the specific germ enters the system at the tonsils or some other part of the nasopharynx.'

"Packard thinks the tonsils act as barriers to such infections. He says during or after tonsillitis complications with typical acute articular rheumatism may appear. He considers rheumatism an infectious disease, dependent upon a variety of bacteria, and the phenomena of the disease to be due to toxic absorption. He says that it is probable that the toxin causing rheumatism may be produced by an attenuated microorganism, and the frequent entrance of the microorganism by the throat may explain the occurrence of acute articular rheumatism instead of ordinary septicæmia or pyæmia. The present state of our knowledge on the relation of tonsillar affections to rheumatism might be summarized as follows: (1) It is undoubted that a certain number of cases of acute rheumatism are preceded by an angina in a proportion varying from 30 to 80 per cent.; (2) Both rheumatism and angina have many etiological points in common—season of year, cold, wet, fatigue, depression, vitiated air, etc.; (3) The connection of angina and rheumatism, though undoubted in a number of cases, is not yet clearly established; (4) The tonsil may be the port of entry of the rheumatic virus, although the naked-eye appearance of the throat gives no indication of its being affected; (5) The particular affection of the throat which is associated with rheumatism is not yet established. Apparently it is not peritonsillar abscess (quinsy); (6) Peritonsillar inflammation does not appear to be arrested by the administration of anti-rheumatic remedies. Many cases of parenchymatous and lacunar tonsillitis, on the contrary, are considerably benefited by the administration of salicin or salicylate of sodium. That this action proves the rheumatic nature of the disease cannot yet be accepted; (7) The question requires further research in two directions: One in differentiating the various forms of angina, and settling the one which is associated with rheumatism; the other in further research to discover the true nature of rheumatism."

I incline rather to the theory of Packard that different microorganisms are capable of causing rheumatism. But I do not believe that the relation of tonsillitis to it is either that of cause or effect, but that the tonsillitis is produced by the same germs the faulty or imperfect elimination of whose toxins causes the rheumatism.

When toxins are not properly eliminated they produce unpleasant symptoms, according to the part in which they are retained. These toxins may be the waste products of the foods ingested or the toxins of microorganisms. In the blood they may cause headache and migraine; in the muscles and in the joints, what we call rheumatism; about the nerves, neuralgia. Rheumatism is affected by the ingestion of putrid matter, and by atmospheric changes interfering with the proper elimination of the skin.

In an infectious tonsillitis the cause is evidently some germ. The activity of any pathogenic germ may be destroyed by the secretions of the mouth, or by bacteriolytic action of the lymph corpuscles in the various adenoid structures at the entrance of the respiratory tract, without causing much inflammation. I think it is possible for pathogenic germs in invading the body by way of the tonsil so to overexcite its function as to produce a follicular tonsillitis, the severity and extent of which depend upon the virulence of the infection, and the ability of the lymph corpuscles in the tonsil to overcome the infection by exerting their bacteriolytic or antitoxic action.

Thus, I believe that often a person escapes the infection of the original disease by having a follicular tonsillitis. If nature fails to cope with the disease, we may have either a mixed infection, the tonsillitis complicating the disease, or, if the infection enters the body at some other point than the tonsil, the typical disease without the tonsillitis.

I believe the lymph corpuscles in the tissue of the tonsil produce some substance which has a bacteriolytic or antitoxic action, and is, in a measure, an antitoxin. This theory is but along the line of recent developments in the pathology of infection. The study of tetanus has shown that an emulsion of nerve tissue in normal salt solution is in a measure antitetanic.

Roux and Boul believe that the cells of the body are phagocytic, and are capable of destroying not only the bacteria, but also their toxins. The theories of Metchnikoff are well known. Ehrlich is the great advocate of the chemical theory.

Russell of the University of Wisconsin has recently shown that the waste substances thrown off by the life processes of germs form, when in solutions, poisons, which destroy the germs that produce them.

The study of venoms has also thrown light on the study of the interactions of cells and toxins. Various secretions of the body have been found antitoxic to venoms.

That the germs of many infectious diseases can set up a follicular tonsillitis in persons exposed to the original disease, whether they are immune to it or not, is of frequent observation. Cases where one or more members of a family have scarlet fever and others have sore throats, or a tonsillitis, are quite common.

For example, in a family of five persons, consisting of the father, mother, and three children, aged fifteen, twelve, and ten, respectively, during an epidemic of scarlet fever, the father had a slight sore throat, the mother and oldest child a typical follicular tonsillitis, and the two younger children typical scarlet fever, complicated with follicular tonsillitis. They had never, any of them, had scarlet fever before.

Recently a case came under my observation in which laryngeal diphtheria was overlooked, partly because three other members of the same family were suffering at the same time with follicular tonsillitis. In this case, in which the trachea was filled down to the bifurcation with a membrane, there was no sign of trouble in the tonsils, showing the infection originated in the larynx.

Various authors classify tonsillitis differently, some giving a separate etiology for each variety, namely, tonsillitis, follicular tonsillitis, tonsillar abscess, pseudomembranous angina, etc. I believe the etiology of all to be the same, the different forms being due to the virulence of the infection and the kind of tissue involved; but we must have, except in those cases which are aborted in their very inception, the characteristic exudation from the crypts of the tonsil.

A membrane having a texture, or one that is adherent and cannot be removed by a swab, the tissue beneath bleeding when it is removed forcibly, is diphtheritic. Diphtheria does not always commence on the tonsil, but a follicular tonsillitis never commences anywhere else.

The adherent membrane of diphtheria can be demonstrated microscopically to be a network of fibrin, which takes the place of the epithelium covering the mucosa. Most authorities regard it as a product of the epithelium. It does sometimes extend to various depths into the lacunæ of the tonsil and into the excretory ducts of the mucous glands; but the great point is that, though it may extend into the lacunæ, it never exudes from them in the manner of a follicular tonsillitis. It is apt to spread rapidly to the palate, uvula, and wall of the pharynx, it is grayish, and often becomes hard and fibrous. It is difficult to get a good description of diphtheria in a recent author so much has the disease become confounded with follicular tonsillitis.

The Klebs-Loefler bacillus is the microorganism which causes diphtheria and produces the adherent membrane. This bacillus is, however, sometimes found in the human throat when the subject is evidently not suffering from diphtheria. This fact, however fortunate it may be for the subject, throws a doubt upon what would otherwise be undisputed evidence of diphtheria. Haebner reports twenty cases in which the bacillus was found in the mouth and throat of children who presented no symptoms, either general or local. The bacilli often remained for weeks, in one case for two and one-half months, yet in some cases were so virulent, when cultivated and inoculated into animals, that they caused the death of the same in twenty-four hours. The very fact that they disappear at all would show that there is some process going on that is antagonistic to their growth.

It appears from the study of the investigations of Fraenkel, Roux and Yersin, A. de Simoni, and others, that the Klebs-Loefler bacillus is found in different degrees of virulency, and that its virulence can be modified by cultivation.

We all know that another toxin, that of cowpox, is found in varied degrees of virulency, and that very few of the products are equal to that taken directly from the human body. I have found from experience that the boasted light results of certain products are due to their weakness, and that they would often fail when a more potent vaccine would be successful. If this is true of cowpox, it is quite plausible to suppose that the Klebs-Loefler bacillus may be found at times non-virulent, and, if able to produce any toxin at all, it would be so weakened as to be overcome by the normal secretions of the mouth and throat. That the Klebs-Loefler bacillus causes the development of a membrane which has certain characteristics which never vary would seem more plausible than that it should have variable ones, such as sometimes having a texture and again not, being adherent in one case and in another not.

We know that when the bacillus is grown artificially it assumes certain charactersitics which are diagnostic.

There is no doubt in my mind that the Klebs-Loefler bacillus is often present in cases of follicular tonsillitis, and that if more bacteriological examinations were made it would be more often demonstrated.

In writing of herpetic tonsillitis, E. J. Moure of Bourdeaux says: "The only diagnosis of importance or especial difficulty is that between the disease under consideration and diphtheritic tonsillitis. Bacteriologists say that all that is necessary is to cultivate a small piece of the false membrane in order to obtain indubitable results in twenty-four hours. Without wishing to deny that a certain number of cases of diphtheria may have been taken for tonsillitis, I believe that it is, up to the present time at least, impossible for the clinician to accept all the deductions of the bacteriologist, for it has been shown that the Klebs-Loefler bacillus exists in many parts of the buccal cavity of healthy individuals. It is necessary, therefore, to take into account the clinical facts and to be able to associate them with the results of the bacteriological examination."

In 1889 and 1890, Roux and Yersin isolated a diphtheritic toxin, which developed symptoms identical with the Klebs-Loefler bacillus. Probably this toxin must always be formed, whether the bacillus finds its culture media in the human throat or whether it is cultivated artificially for the inoculation of animals, before we can have the characteristic symptoms of diphtheria.

Is it fanciful to suppose that the lymph corpuscles develop a toxin that is antagonistic to the formation of diphtheritic toxin, yet in their activity to resist infection cause a follicular tonsillitis? This may account for the presence of the Klebs-Loefler bacillus in cases in which the clinical symptoms are evidently those of follicular tonsillitis. That no specific microbe is found rather goes to prove my theory that the tonsil has something to do with the production of the toxin —or antitoxin, I might call it. It is evident from the course and symptoms of the disease, and the fact that it is directly infectious itself, that the toxin is identical in all cases of tonsillitis, although it is caused by various organisms.

It is well to note here that one attack of scarlet fever or measles usually protects the body against a subsequent infection of the same disease. The fact that this is not so in tonsillitis shows that the diseases are radically different in their nature. I have seen it attack each member of a family year after year for many years, but recently, from better understanding the contagious nature of the disease, I have been more often able to confine it to a single person.

I do not wish to say that diphtheria could not develop from a simple follicular tonsillitis, but I think those cases must be rare indeed. I can give evidence of five hundred cases in which it did not. When there is diphtheria it is probably present from the very beginning. I do not believe that it can develop without producing characteristic clinical symptoms, and that it is not virulent unless it does.

I will relate one unfortunate case which illustrates some of these points:

Case I.—A family of five persons, whom I had treated for follicular tonsillitis at least once a year for six years previously, were having their usual experience with the disease. The cases were all light, except that of the father, who had a bad peritonsillar abscess, which he had frequently had as a complication before. A young man of thirty, of remarkably fine physique, was visiting at the house, and he also contracted the sore throat. He had been subject to tonsillitis since a child. He consulted his physician, who took a swab from his throat and had a bacteriological examination made. The young man had sat up the greater part of two nights with the father, who was unable to sleep, and suffered a good deal with his bad quinsy. The Klebs-Loefler bacillus was found by the health department. The young man had been invited to stay at the house, as the family felt responsible in a way for his sore throat. So he went home to get his things, and returned to the house about four o'clock. His physician visited him at five o'clock, bringing with him the results of the bacteriological examination, and then injected, with every antiseptic precaution, 1,500 units of a standard antitoxin into the region of the abdomen. In a minute the young man was seized with a choking feeling about the throat and a desire to defecate. He was then immediately seized with convulsions, and died in ten minutes. I was unable to reach the house in time to see him alive.

The post-mortem examination was very unsatisfactory, except that every organ was found to be in a healthy condition. The other physicians present evidently thought he died of diphtheritic poison, and, from motives of delicacy, I was unable to suggest any other cause of death. I should like to have seen the tonsils, on which the only evidence of the disease shortly before death were a few discrete patches. Of course, the doctor, from the present knowledge of bacteriology, was perfectly justified in giving the antitoxin. But I, in the future, as I have always done in the past, will place a great deal of dependence upon clinical symptoms,

I hesitated in reporting the case, fearing that by including it in this paper I might arouse the suspicion that I was prejudiced against the use of antitoxin. I believe it to be one of the most valuable remedies that has yet been discovered, and that its discovery along scientific lines of investigation and its successful use show great promise for serum therapy. But I wish the fact that it is a potent remedy, and not a harmless drug to be recklessly administered, to be well known. I fear that the alarming symptoms and fatal results that sometimes follow its use have not been sufficiently reported.

Some observations that I have made since writing the above lead me to suspect that the hæmolytic effect of carbolic acid or some other coal-tar product, used as a preservative of the antitoxin, or accidentally left in the syringe after cleaning, may account for some alarming symptoms following the use of antitoxin.

I believe antitoxin is given ten times in follicular tonsillitis where it is given once in diphtheria.

I have given it five times in cases in which children have been exposed to supposed diphtheria, and in which the cases had been reported and quarantined as such. Four of these patients developed follicular tonsillitis.

Case II.—The F. children, aged six and four, played with a child who was sick with a sore throat. The following day the physician attending the sick child, from a bacteriological examination, pronounced the case diphtheria. I injected 500 units of antitoxin into the gluteal region of both children; a day later the younger child developed a typical case of follicular tonsillitis.

Case III.—The E. children, aged seven and five, played in bed with a child who, on the following day, was pronounced to have diphtheria. I injected the antitoxin, but both children came down with severe cases of follicular tonsillitis. An aunt in the family also had tonsillitis, which was complicated by a peritonsillar abscess. The E. children have since both had scarlet fever, the lighter case complicated by tonsillitis; the severer case was uncomplicated, except that the scarlet fever intensified a pre-existing nephritis, which almost proved fatal.

Case IV.—Three M. children played with a child who had diphtheria, but as the two older children had had diphtheria, I injected the youngest alone, One of the older children developed a follicular tonsillitis.

I will not try to enumerate the number of cases of tonsillitis in which similar former attacks, according to the patient's story, were diagnosed as diphtheria. I surely cannot be alone in my experience.

I have seen almost no diphtheria in ten years of practice, yet there is hardly a nurse whom I have questioned, if she has had a year or two of experience, who has not seen several. One nurse in particular gave me the histories of six cases with whom she had been isolated, and which were the total number she had seen. In but four of these cases was there any evident patch, and in these it was easily removed by a swab. To three of the patients antitoxin was given, but all the cases were very mild. Such evidence seems to point to the fact that many cases are diagnosed as diphtheria which follow the clinical symptoms of follicular tonsillitis.

Although follicular tonsillitis is primarily an affection of the tonsil alone, we may have a great many complications from the extension of the inflammation to the surrounding tissue.

Abscess of the tonsil itself, peritonsillar abscess, and otitis media are quite common. The mouth gums and salivary glands may become infected, giving all the symptoms of salivation.

Severe septic inflammation and œdema of the throat may follow a tonsillitis. From extension to the respiratory tract, we may have laryngitis, bronchitis, etc. In eliminating the poison, the kidney may become the seat of an inflammation. That it frequently complicates scarlet fever, epidemic influenza, I have mentioned, but in these cases it is not the original disease. I have never seen a case of follicular tonsillitis develop the clinical symptoms of diphtheria.

The only other bacilli capable of producing a membrane similar to that of the Klebs-Loefler bacilli are some of the pyogenic cocci.

When the streptococcus pyogenes is the cause of the follicular tonsillitis the diagnosis from diphtheria is extremely difficult, as the appearance of the membrane formed is almost identical with that of diphtheria.

The streptococcus pyogenes is the constant attendant of the so-called diphtheritic scarlatina. If the rash is slight or absent, as it is sometimes in atypical scarlet fever, one is very apt to be misled in diagnosis. The membrane is somewhat adherent, and seems to have texture, but it can be removed by a swab, and the texture is more apparent than real. It may become quite adherent later, while if seen early enough, it is quite easily removed.

It is in these cases that a bacteriological examination is of great aid in making a differential diagnosis. I have such a case at present under observation, and the extreme difficulty of diagnosis is well shown in the difference of opinion of my consultants.

I will not detain you with a description of the course and symptoms of the disease. I have mentioned the main symptom which, if present, is diagnostic. The systemic symptoms are those of infection of the body by some poison. It is worthy of note that the fever is high in proportion to the bodily depression, and that the patient often feels worse before the exudation is much in evidence. That one tonsil often escapes infection, and that disease can be avoided by preventive local treatment, is interesting.

As to treatment, I think we should go on the theory that nature is trying to eliminate a poison. Locally, the exudate should be removed as soon as it is found, best with a dry swab, but the peroxide spray is very effective, and is more convenient for the patient to use.

Some antiseptic wash or spray may be used, but I have generally found the peroxide sufficient. The patients are usually constipated, and calomel is best given at once.

The drug I have found of the most value, probably because it is such a good eliminant, is the salicylate of sodium. Aconite and belladonna are useful.

The headache and pain in the back and limbs are quickly removed by the coal-tar products. The various complications require their different treatments. I have no experience with nuclein and other gland extracts in the treatment of tonsillitis, but I think, theoretically, they should be of service.

On the whole, I know of no disease which is so satisfactory to treat and which is so amenable to proper treatment.

The severity of the disease seems to depend somewhat on the length of time since a previous infection, showing that a variable period of immunity is caused by one attack.

In writing this paper I do not wish in any way to decry the great value of bacteriological examinations, but rather to urge their use even on non-clinical cases. I have recently found them of great value in confirming a negative diagnosis when the history of the case seemed to point almost conclusively to diphtheritic infection. This case being in an institution where a large number of children were exposed, the question of diagnosis was of the utmost importance. In very mild cases of diphtheria the patches may be so small as to be difficult to distinguish from the exudative plugs of tonsillitis; and if I found a patch in which there was any question of its adherence or texture, I would call it diphtheria, even though the Klebs-Loefler bacillus could not be demonstrated, for the not finding of the bacillus in cases of clinical diphtheria is due to faulty technique.

But I do wish to point out the fact that the clinical symptoms of follicular tonsillitis are radically different from those of diphtheria, and that the presence of the Klebs-Loefler bacillus in a non-virulent form is not conclusive evidence that the case is diphtheria. Landowzy, in the results of 860 cases examined bacteriologically, concluded that it was impossible to diagnose clinically many throat affections from diphtheria. In this conclusion, I take it, he was confounded by the presence of a Klebs-Loefler bacillus in many minor throat affections.

My views on the value of antitoxin I have given. I think it is a fact to be greatly lamented that, notwithstanding all the clinical evidence of its great value in diphtheria, there are still to be found physicians to oppose its use. I do not claim that it does any harm if given in follicular tonsillitis, but what I am after is the truth, and if its value as a remedy has been overrated by including in the statistics cases of follicular tonsillitis, I should like this fact to be known.

I do not wish to underrate the importance of the removal of hypertrophied and diseased tonsillar tissue. But great judgment should be used in all cases, and if the hypertrophy is caused by overwork, due to diseased nasal mucous membrane, that should be treated first. No more tonsillar tissue should be removed than is necessary. It might not be out of place to say here, that while the removal of the tonsil will prevent the recurrence of tonsillitis, in so far as the crypts are entirely removed and the follicles that cause the characteristic symptoms are gone, yet, in my experience, it will not protect the body against subsequent attacks of sore throat, or any of the infectious diseases that gain access to the body by way of the tonsil.

In closing, I will recapitulate a few points I have endeavored to present:

1. That follicular tonsillitis is not caused by a single microbe, but that many well-known microorganisms are capable of causing it.

2. That the symptoms of tonsillitis are partly caused by an exaggeration of its function.

3. That under the stimulus of infection the lymph corpuscles in the adenoid structure of the tonsil produce an antitoxin that is antagonistic to invading germs.

4. That the characteristic symptom is an exudate having no texture and non-adherent.

5. That the presence of the Klebs-Loefler bacillus is not positive evidence that the disease is not a simple follicular tonsillitis.

6. Lastly, that there seems to be some relation between follicular tonsillitis and the infectious diseases which is not yet properly understood; that whatever the function of the tonsil, it seems in disease to endeavor by its activity to assist nature in eliminating infection.

I know that in this paper I have digressed considerably from the subject, but I hope you will pardon me if, having taken follicular tonsillitis as my topic, I have endeavored to show in disease that the doctrine of the survival of the fittest is carried down to the smallest cell and most minute microorganism; how every microorganism is ever looking for a place to propagate its kind without reference to the damage it does; how each individual cell endeavors to resist its own annihilation; how groups of cells may become organs specialized to resist infection.

That the tonsil, placed at a vulnerable point, should become injured in resisting infection; that the kidney in eliminating poison should have its function impaired by nephritis; that the blood should leak out into a muscle or joint some of the toxin it is endeavoring to carry to one of the excretory glands, are evidences only of nature's grand system of defense.

A CASE OF PRESENILE OR ANGIOSCLEROTIC GANGRENE PRECIPITATED BY INFLUENZA.

By THEODORE B. BARRINGER, Jr., M.D.,
ASSISTANT ATTENDING PHYSICIAN, CORNELL UNIVERSITY MEDICAL COLLEGE DISPENSARY.

The rather exceptional involvement of an upper extremity and the favorable result of a conservative operative procedure, combined with the administration of large doses of potassium iodide, are the conditions which have made this case worthy of report.

The history is as follows: Mrs. C., aged thirty-eight years, housewife, native American. The father died of enlargement of the heart and dropsy at the age of fifty-seven, and the mother at sixty-two from a stroke of paralysis; the maternal grandfather died from phthisis. One brother has paresis. The patient has had no children. For the past seven or eight years she has suffered from a steadily growing uterine fibroma, necessitating, in 1896, an induced abortion. She has had no other abortion or miscarriage. Her habits are excellent, and there is absolutely no history of specific trouble.

During the fall of 1900 neuralgic pains of a transient character were experienced in the right arm and forearm. In December the finger tips of both hands, especially the right, frequently felt hot, "as if they had been burned." January 8, 1901, patient had an attack of influenza of moderate severity, temperature reaching 102°, and a bronchitis of the larger tubes existing. Unfortunately, no bacteriological examination was made of the sputum. This lasted about one week. January 17, all of the fingers felt "frost-bitten and tingled," especially the fourth and fifth of the right hand. The pain grew steadily worse and localized itself in the latter fingers and the ulnar side of the palm. January 19, forty-eight hours later, the conditions were as follows: The fingers of the right hand were uniformly swollen, slightly reddened about the joints and tender, the palmar surfaces of the last phalanges of the fourth and fifth fingers presented each a small purplish area, exquisitely tender. There were also a few bluish flecks on the ulnar side of the palm, which later disappeared. The patient was delirious with pain, which was partially controlled by one grain of morphine hypodermatically.

Physical Examination.—A small, fairly well-nourished woman, with pallid skin and mucous membranes. Mouth temperature 101°. Examination of the lungs was negative. The heart was of normal size; there were systolic murmurs at the second left space and apex, the latter being transmitted a short distance to the left. (The apical murmur eventually disappeared.) The pulse was of medium size, fair tension, and intermitting every fifth beat; the radials were soft, and pulsation was felt in both ulnar arteries. Examination of the abdomen was negative, except for uterine tumor reaching to umbilicus. The pupils were equal and reacted to light and accommodation. The patellar reflexes were normal. Urianalysis was negative in its results on this and repeated future examinations. The blood showed no leucocytosis; a count of the red cells was not made; hæmoglobin, 65 per cent. (due to excessive loss of blood at each menstrual period).

Subsequent History.—The purplish spots, before mentioned, became areas of dry gangrene, which spread rapidly until the terminal phalanx of the fourth, and the terminal and half of the middle phalanx of the fifth fingers were involved. The remaining portions of the involved fingers and also the other fingers of that hand remained swollen, tender, and very painful, necessitating the subcutaneous administration of about one grain of morphine sulphate daily. The only local applications giving relief were baths of ice-cold, weak solutions of carbolic acid. An irregular temperature running up to 101°–102° toward night was present; on some days the patient was free from fever, the local condition being, apparently, the only explanation of this. Meantime the line of demarcation had formed, and on February 22 the involved phalanges were amputated. The wound healed by first intention and the patient was put on five grains of potassium iodide *t. i. d.*, and hot dry sand baths locally. She gained weight and the pain became much less. In May it returned with renewed vigor in the stumps and the ulnar side of the palm, both of which became swollen and reddened, showing a number of small purplish flecks. On May 22, the stumps, together with the fourth and fifth metacarpal bones, were removed, chiefly on the account of extreme pain, and because it seemed impossible to save that portion of the hand. The wound healed per primam. Microscopical examination of these parts showed that the gangrene was caused by localized arteriosclerosis. Two weeks later the pain returned in the remaining fingers with marked severity. Large doses of potassium iodide and small doses of the protiodide of mercury were then given, and in a few days the pain abated. For two months the condition in the hand was quiescent, and the nails, which during the entire illness had shown no growth, began to grow again. Then there was a slight recurrence of pain which was overcome, following a recent suggestion of Buchner, by the application of bandages saturated in 95 per cent. alcohol, to the hand and forearm. This was continued every day for some weeks; the iodide being still kept up.

At the present time, eight months after the second operation, the pain appears at very infrequent intervals, and is very slight in character. The fingers have resumed their normal size and appearance, the stiffness which persisted for weeks has disappeared, and the hand is used freely and effectively.

The very complete pathological report for which I am indebted to the courtesy of Professor James Ewing is as follows: "The tissues examined included the entire cross sections of the terminal phalanges amputated at the first operation and tissues from the various portions in the metacarpal area removed at the second operation.

"In the terminal phalanges the conditions found were briefly: (1) Advanced pan arteritis, with complete occlusion of the large vessels; (2) Advanced chronic productive interstitial neuritis, resulting in nearly complete sclerosis of many nerve trunks. In addition to the fibrosing process there was extensive infiltration of the tissues with round cells, rather diffusely in the subcutaneous areas, and grouped especially in the sheaths of bloodvessels and nerve trunks. The lobules of fat tissue were extensively infiltrated with round cells.

"In the metacarpal region there were the same changes, but less marked. A section of the artery of the deep palmar arch showed the vessel to be the seat of extensive endarteritis, while its lumen was nearly occluded by a rather recent, partly organized thrombus. The media of the vessel was replaced by a tissue composed of many round cells and new bloodvessels. The intima was much thickened by a cellular growth. The infiltration by round cells of all sheaths of bloodvessels and of epineurium and of perineurium was extreme, while many fat lobules and bundles of muscle fibers showed similar infiltration, often in miliary foci. In some places the collections of round cells showed evidences of beginning necrosis, but no miliary tubercles were discovered. The microscopical appearance, especially the limitation of the process to sheaths of bloodvessels, strangely resembled those seen in specific disease.

"A more acute and intense phase of the process existed about some large vessels beneath the skin of the metacarpal region, which were almost completely destroyed by infiltration with mononuclear and polynuclear cells, partly necrotic. In these areas the condition was practically that of miliary abscess."

The examination of four cross sections of the digital arteries showed two nodular thickenings of the intima projecting well into the lumen and confined to a portion of its circumference. How far these nodes extended in the longitudinal axis of the vessel, and whether they occurred where branches were given off, could naturally not be determined from so few sections.

It is to be noted that the process, as far as could be ascertained, was strictly localized. The radial artery which was very readily accessible to the palpating finger, was perfectly soft, the pulsations in the ulnar artery could be felt, and there were no evidences of arterial disease elsewhere. This marked circumscription of the diseased area, and absence of involvement not only of the chief afferent artery, but of arterial disease in other regions, would seem to place a distinctive mark on this case of angiosclerotic gangrene; for on reviewing the literature of spontaneous gangrene, I find the great majority of cases show an involvement of the main arterial trunk, in the shape of an obliterating arteritis, which is evinced during life by thickening and feebleness or absence of the pulse. Therefore, the apparent absence of disease in the main artery puts our case in a separate class, whose surgical treatment is decidedly different from that of the usual form.

The term presenile or angiosclerotic gangrene includes those cases of spontaneous gangrene arising in young or middle-aged persons from localized arterial disease as opposed to cases due to senility, diabetes or to neuropathic causes. The primary etiology of this group of cases is still somewhat obscure, a divergence of opinion existing as to whether the causes of generalized arteriosclerosis are also valid here.

The secondary or local causes have been carefully considered by, especially, v. Winiwarter, v. Zoege-Manteuffel and, of late, Bunge. V. Winiwarter, the first to make thorough investigations, ascribed the gangrene to an obliterating endarteritis, which of itself, was sufficient to cut off the blood supply without the intervention of a thrombus. V. Zoege-Manteuffel says: "The arteriosclerosis has existed in the patient for some time. It is accentuated through injury of a chemical, thermic or vasomotoric in character. The intima grows, but cannot of itself lead to a closure of the vessel, the blood current preventing this. On the contrary, some cells of the intima are loosened, roughness of the wall ensues, on which coagulation thromboses form, and are organized."

Bunge in his last article advances a somewhat different theory, as follows: "On the basis of a sclerosis of the artery there arise circumscribed sclerotic thickenings of the intima, which narrow, usually in many places, the vessel lumen. These stenoses develop generally at the places where branches are given off, and so form an obstacle to the development of a collateral circulation, thus endangering the life of the part supplied. Behind these stenoses thrombi form, thus cutting off the circulation entirely."

Among the cases he most minutely describes in support of his theory is one, Case III, whose pathological findings present, in addition to the above-described lesions, certain other changes in the media and adventitia, quite similar to those found in our case. These changes, taken in connection with lesions in other organs, induced Bunge to make a tentative diagnosis of syphilis in his case.

Thus it is seen that the microscopical examination of our case, while corroborating the views of v. Zoege-Manteuffel, was not extensive enough to permit of an expression as to the correctness of Bunge's theory.

The attack of influenza undoubtedly afforded an impulse sufficient to precipitate the thrombosis in arteries, which, from the nature of the lesions found, had been damaged long before. Eichhorst, in a recent article, has collected reports of nineteen cases of gangrene following influenza, and many cases following other infectious diseases. The involvement of the vessels' sheaths, the extensive neuritis, both unusual in ordinary presenile gangrene, and the excellent results following the exhibition of iodide and mercury, certainly suggest a specific origin for the trouble.

Of the symptoms, the neuralgic pains, preceding by some months the attack, and the absence of intermittent claudication, are to be remarked. The cause of the agonizing pain, present at intervals for weeks, is possibly to be explained as follows: On each occasion the patient would exclaim that the fingers felt "as if they would burst." Then with the acme of pain they would become more swollen and purplish red in spots, the circulation apparently experiencing a transient disturbance. The increased pressure thus exercised by the congested bloodvessels on the nerve filaments, already inflamed, would appear to explain this most distressing feature of the case.

A few words concerning the treatment, both medical and surgical. Following the first operation, small doses of potassium iodide and locally hot, dry sand baths were given with a view to influencing the peripheral circulation. This had no effect, probably on account of the advanced disease of the remaining portion of the ulnar area, which was accordingly removed at the second operation. Then the large doses of iodide (gr. xx daily) and the small doses of mercury were given, with the gratifying result before mentioned.

The blood pressure at this time, as estimated by Gaertner's tonometer, showed 101.5 mm. of mercury for the affected right hand and 115 mm. for the healthy left hand, thus showing that the digital arteries of the right hand were sufficiently diseased to produce a local decrease in pressure.

Following a recent suggestion of Buchner, bandages saturated in 95 per cent. alcohol were applied to the hand and forearm for thirty minutes, and the blood pressure then taken. The effect was shown in a local increase of pressure amounting to 10 mm. of mercury, thus demonstrating absolutely the remarkable action of external applications of alcohol on the local blood pressure. The propulsion of more blood through the diseased area must certainly aid materially in re-establishing normal conditions. This treatment was accordingly steadily persisted in. After six weeks of the treatment the blood pressure in the affected area varies between 108 and 115 mm. of mercury, which, compared with the former pressure of 101 mm., shows a most decided improvement.

As regards the surgical treatment. The textbooks and literature advocate, almost without exception, a high operation in spontaneous gangrene, that is, an amputation some distance above the line of demarcation. The disadvantage of the low operation lies in the disposition of the flaps to slough and start a new process of gangrene at the line of incision. Von Wiedenmann advises a low operation in all cases, with the proviso that if the main artery is completely or partly occluded, or if the flaps bleed but little, to do a high operation. Certainly, in cases like ours, with a circumscribed lesion, and healthy or comparatively healthy main artery, the low operation is much to be preferred. The first operation (removing the gangrenous phalanges) did not end, as we hoped, the surgical interference. Although the flaps bled but very little, they healed by primary union. The severe pain and evidences of marked circulatory disturbances in the ulnar area decided the second operation. We now had a portion of the right hand left, the preservation of which was naturally of extreme importance to the patient. The appearance of the hand and the decreased blood pressure showed that the entire area of disease had not been removed, and it was now our task to improve this poor circulation. This, I think, was done very effectively by the abovementioned medical treatment.

The good condition of the patient at present, eight months after the last operation, is a very favorable comment on the advantages of conservative treatment in this particular class of cases, and a happy outcome to a most interesting case.

DISCOVERIES IN PATHOLOGY.

By MARY DIXON JONES, M.D., F.R.M.S.,
NEW YORK CITY.

Pathological structures are secondary formations. Sometimes they are exceedingly changed and varied, and again they may show great resemblance to the original tissue. They can never perform the natural physiological functions, yet they are human tissues, and there is a great and fascinating beauty about these new formations. Under the microscope they show marvelous combinations, and are wonderful in their anatomical make-up.

Once in studying a profoundly diseased ovary, with a power of 400, there was presented a picture of almost dazzling brightness: Long-branching protoplasmic bodies of exceedingly delicate and exquisite organization, winding in all directions, and in most graceful curves. It made a fairyland of beauty. It was a forest of wonderful structures. But the ovary! In it was found no normal tissue. Large portions were transformed into this peculiar growth, which was filled with coarse granules, hæmatoblasts, and other life material, proving its innate powers and, possibly, its destructive tendencies.

All such changes necessarily give rise to great suffering and to serious constitutional disturbances. There can be no great pathological change of tissue without abnormal conditions of the system, and always great light can be thrown on these changes and new formations by considering the clinical history of the individual. The microscope reveals the pathological change, clinical history gives the life reflection, and makes the momentous reverberations of the almost tragic records. Without the clinical history, there can never be as clear an understanding of any great pathological process or formation.

The patient in whose ovaries this growth was said that for fifteen years she had suffered distress in the pelvis, and that she had been refused admission into two hospitals. I told the patient I would receive her into my private hospital, and give her any treatment or perform any operation that might be necessary for her welfare and recovery. The next day, June 18, 1885, she entered, thirty-five years old, single. The ovaries gave evidence of profound disease and serious pathological conditions. I saw they never could be restored to health, could never again perform their physiological functions, and would be only a source of increasing distress, doing more and more injury to the system, and the only right course was their removal.

After removal, the organs were prepared by the best methods for microscopical investigation. But this growth, that could apparently spread and destroy every tissue of the ovary, what was its nature? I thought at first it was carcinoma. The master of the laboratory pronounced it "sarcoma," and afterwards "sarcoma or endothelioma." It was evidently formed by the breaking down of normal tissue, and from these primal or medullary elements any new growth may be evolved. The formation finally received the name of endothelioma, from its supposed resemblance to the lining endothelia of the peritoneum and of the blood and lymph vessels.

On March 30, 1887, a mother brought her daughter to me, pale, emaciated, and apparently with tuberculous consumption. I did not then imagine I was going to have another revelation of this peculiar disease. The patient said she suffered with constant and distressing pain on both sides of the pelvis, that she had been married some years, and had no children. This patient had been treated by many excellent physicians, both locally and constitutionally. I also commenced a course of treatment, but was soon compelled to inform the patient and her husband that the organs never could be restored to a normal condition, or made capable of normal functions, and that there was no way of relief but by their removal.[1]

These ovaries proved to be mines of pathological wealth; rich fields for investigation. There was this growth in an advanced stage of development extending to the periphery, and in the spaces other pathological formations. There was not one spot of normal tissue in either ovary.

The patient made a rapid recovery from the operation, and her sister, who had the same trouble, without an operation, soon died.

I presented before the New York Pathological Society the ovaries and tubes, and a number of mounted microscopical sections of both organs. I continued studying this peculiar growth by different powers of the microscope, and during the summer of 1887 could see that the coarse granules of these protoplasmic bodies were shaping themselves into blood corpuscles and bloodvessels. This was a wonderful revelation. It was the formation of a blood cyst, a hæmatoma. Again and again I traced out these pathological changes, made repeated drawings of the same, and presented the subject before the same society, December 12, 1888.

A hæmatoma of the ovary is not a hemorrhage. It is a growth, a pathological formation, evolved from an endothelioma.

I soon found that endothelioma was a frequent disease and had well-marked symptoms. In many instances I have diagnosed it on first examination, and the diagnosis was subsequently verified by the microscope. From the examination and investigation of many cases, it was more and more proved and demonstrated that this disease was destructive to the general health and life of the patient; so much so that I began to think it was malignant, and, at that time, said: "When we look at this rapidly growing formation, the great mass of granules, the impression forces itself upon us that it may be malignant. Cancer epithelia do not multiply more rapidly or destroy the tissues more surely, or seem more threatening or monstrous in their appearance and growth."

Near akin to endothelioma is a formation known as gyroma: large, convoluted masses, sometimes extending through the entire length of the ovary and filling much of its area. They are composed of fine anatomical structures, and present a most interesting study for investigation.

The first time I recognized this formation was in 1887, when I was making microscopical researches in certain diseased ovaries, and on September 14, 1887, I presented the same before the New York Pathological Society as formations of dense fibrous connective tissue or fibromata. The patient was feeble, emaciated, chachectic, and had all the appearances of phthisis, but I could eliminate disease from every organ except the ovaries, and these I found in a state of profound disease, one being enlarged to the size of an orange and bound down by firm adhesions. This proved to be a blood cyst, and ruptured on removal. The patient made an excellent recovery, was relieved of pain, gained flesh and strength, looked well, all appearance of phthisis disappeared, and she was able to resume her ordinary duties.

We see from the above case how this mysterious disease destroys the health and comfort, and produces most profound constitutional derangements.

The second patient in whom I found this peculiar formation, gyroma, consulted me August, 1888. In November of that year, while studying the pathological specimens removed from this patient, there were seen these immense fibromatous formations, or, as we afterwards called them, anomalous menstrual bodies, and which I now designate gyroma. I presented the specimens before the New York Pathological Society December 12, 1888, and made the following statement: "The right ovary was much enlarged, and most of it was occupied by a fibroid growth or tumor, while in other portions there were a number of small nodular fibromata, in the neighborhood of which the bloodvessels were much enlarged." I then remarked: "The subject of normal and abnormal menstrual bodies is an unexplored field. It presents points not only of great scientific interest, but of momentous importance. It reveals the cause of the exhausting and untold suffering which many women endure year by year, often developing other and more serious troubles, and finally carrying many to the grave."

Gyroma is not only a cause of suffering, but a cause of constantly increasing distress and trouble. In 1887 I recognized that in gyromatous formations nerve fibers were often imprisoned and compressed, and thereby became a source of pain and great suffering. I mentioned this in an article in the *American Journal of Obstetrics*[2] and then said: "It is the first time, so far as I know, that nerve fibers have been traced in these formations."

In the same article I called attention to the pathological condition of diseased bloodvessels in the ovary. The various diseases of these bloodvessels and the serious pathological changes presented by the arteries have for years been subjects of great interest and study to me. In a paper at this time,[3] I tell of a patient who came to me in 1885, an abscess in the left ovary and pyo-salpingitis of the tubes. I found the endothelia of the arteries and the muscle coat both entirely reduced to inflammatory corpuscles. This would at once destroy all functional capability of these arteries; and who can tell what might be the disastrous results? Another case mentioned in the same paper, a patient who had pyo-salpingitis, I found the arteries of the left ovary in a state of waxy degeneration. Another patient, with abscess of the left ovary and chronic salpingitis, the middle coat of the arteries were in waxy degeneration, the calibers very much narrowed, and in some instances entirely closed. Others showed artheritis and endarteritis obliterans, with consequent formation of fibrous connective tissue.

Mixomatous Degeneration of the Ovary.—Mixomatous tissue is the earliest formation in normal embryonic development. It consists of a reticulum of living matter; so, in itself, it is almost infinite in its capabilities and possibilities. In its anatomical structure it resembles malignant growths, and shows a great similarity to sarcoma and myxo-sarcoma Besides, patients who have this form of degeneration seem in their constitutional conditions as seriously disturbed as if they had malignant disease; each one gives evidence of great distress and local pain.

All the vital structures of the ovary may be displaced and destroyed by this remarkable form of degeneration. It seems to have a withering effect upon every anatomical element.

On March 25, 1896, I presented before the New York Pathological Society this form of degeneration of the ovary, and microscopical sections showing the same. The transactions of the society, as they appeared in the MEDICAL RECORD, September 5, 1896, say: "A new form of degeneration of the ovary, by which most of the organ was changed to myxomatous tissue. Out of over eighty pairs of diseased ovaries examined, there have been found four pairs showing this degeneration. This condition was associated clinically with marked deterioration of the general health."

Professor Waldeyer wrote me May 18, 1896: "I have never seen a myxomatous degeneration of the ovary; perhaps it has hitherto not been seen by any one."

Diseased Ova.—The great subject of diseased ova was first unfolded to me in 1885. A patient came from Maine to consult me in regard to a fibroid tumor of the uterus. Dr. Chas. Carroll Lee was present at the operation. The ovaries were three times their normal size, and projecting from each was a cyst, size of a hen's egg. It was in those ovaries that I recognized for the first time diseased ova. I do not know of any one ever before having mentioned the fact of the human ova being diseased. Many of these little organizations were reduced to medullary corpuscles, their entire anatomical structure destroyed. As I continued my researches, studying the pathological conditions of the ovaries of my patients, I had repeated occasion to note that the ova were abnormal and exhibited many forms of degeneration. Dr. G. E. Herman of London wrote me, "You are digging new ground." It was, indeed, a sad find, and a new cause of sterility in women. It presented also a most important field for investigation.

No doubt one day the diseases of the ova, their marvelous forms of degeneration and destruction, will be considered one of the most important chapters in the pathology of the ovary. The ova are not only highly organized, but they are masses of living matter, and for them the ovary really seems to exist.

One of the most remarkable diseases of the ova is colloid degeneration. This peculiar form of degenertion seems to have the power of making complete destruction of these fine and beautiful organizations. Sometimes only a dot or fold of colloid substance is left; then there would be fields with not one ovum; then again fields in which masses of ova are almost destroyed by this degeneration, all presenting a most picturesque appearance of ruin and desolation. While in sections of the ovary I have counted 140, 160, and 192 ova, but when there is colloid degeneration, many sections placed under the microscope there will be extended fields and not one ovum.

Ovarian Cysts.—One of the first observations I made in studying pathological ovaries was the intense inflammation invariably seen around a cyst. In June, 1889, when I was about finishing my microscopical investigations in colloid degeneration of the ova, the thought was forced upon me. I could see again and again the intense inflammation in the cyst wall, and in every instance when the cyst wall was thus inflamed, it was separating, crumbling, and the parts passing into the cyst fluid. Inflammation is the beginning and the origin of ovarian cysts—the only condition that can produce a cyst of any kind. The more intense the inflammation, the more rapid the growth of the cyst.[4]

The Origin and Formation of Myo-fibroma of the Uterus.—I have proved that fibroid tumors of the uterus are the outgrowths of, and caused by a diseased condition of the uterus.[5]

The Fallopian Tubes.—Many months I have spent in trying to look into the anatomical structure, normal and pathological, of these organs. I have demonstrated that there are six layers of muscle in the normal tube wall, instead of three, as is usually given. By this abundant supply of muscles, the tubes are enabled to perform their various and complicated functions.

The mucosa lining the tubes form numerous folds, almost infinite in number, thus giving a vast extent of surface, upon which are millions of cilia; each one of marvellous formation, containing living matter, and capable of vital functions more important than we can imagine or realize. These cilia are in incessant motion, helping constantly to carry the burden of the little ova to the uterus. Also by the continued motion of the cilia, a constant current is produced which tends to sweep out impurities that might find their way through and from the uterus into the peritoneal cavity. This requires free muscular action. In 1887 I traced out this wonderful net-work of fine muscle fibers in the mucosa.[6]

I have repeatedly seen all the immense and complicated apparatus of the tube wall breaking down into inflammatory corpuscles, and, to a great extent, transformed into granular protoplasm. Sometimes not a muscle bundle, or fiber, left in the whole wall, only broken remnants scattered in a sea of inflammatory corpuscles; the intense inflammation destroying all normal tissue. I have also had cases, in which not only the whole muscular structure of the tube wall was destroyed, but in the wall many miliary abscesses. Can a tube so diseased, its anatomical structure so changed, and destroyed, and the tube already filled with pus, be made to perform its normal functions? The muscles and the mucosa are gone; they will no more appear. We may draw off the pus, but the pus will come again. The tissues are pus producing when normal tissue is gone. Impossible for such a tube to perform its natural functions.

Cancer.—In 1893, in studying a case of "Carcinoma on the floor of the pelvis,[7] I saw clearly that the inflammatory corpuscles were changing to cancer epithelia. This I demonstrated repeatedly. It was a wonderful revelation; and, as far as I know, had never been recognized or mentioned.

Also, by a power of 700, I saw that the lymph vessels were carrying the cancer epithelia.

This, by the clear light of the microscope, was repeatedly proved, by powers of 600, and 1,000. Yet Virchow says:[8] "The infection is directly transmitted by means of the morbid juices, from the original seat of the disease without the intervention of vessels or nerves."

But the microscope plainly shows that the lymph vessels are carrying the infection. They are carrying the epithelia with all they contain "from the original seat of infection."

The eminent John Marshall of London speaks of "The acid juices of cancer, and the mode in which they penetrate into the vacuities of living tissues." F. A. Purcell says: "Cancer cells show amœboid movements, and can thus travel independently in tissue spaces."

But do not both "the acid juices" and "the amœboid cells" travel with, or by means of, the epithelia in the lymph vessels? They thus can go to every part of the system, "penetrate delicate membranes" and "the vacuities of living tissues."

We see the lymph vessels crowded and packed with cancer epithelia. They are carrying their burden of malignancy and death. They are even giving to the vessels themselves their deadly poison. The endothelia are in active proliferation, and the deadly disease is extending to the surrounding tissues.

Sir James Paget talks of "micro-parasites." But whatever may be the germs or microbes, it is the cancer epithelia that are doing the fatal work. Dr. G. F. Shrady said, in the MEDICAL RECORD, November 23, 1891, "Bacteriology had not succeeded in incriminating any microorganisms as the causative agent of carcinoma."

REPORT OF FIVE CASES OF ULCER OF THE ŒSOPHAGUS, DIAGNOSED AS PULMONARY TUBERCULOSIS

BY MARK I. KNAPP, M.D.,
NEW YORK.

VERY meager indeed is the literature on ulcer of the œsophagus. Textbooks, as a rule, devote but a fraction of a page to this disease which in my experience has proven by far more frequent than ulcer of the stomach. Indeed, regarding pathology, the entire œsophagus has been treated with a sort of contempt. The symptoms of œsophagitis—pain between the shoulder-blades or pain behind and along the sternum—are eagerly interpreted by that highly poetic, mystic, and euphonious phrase "reflex pain," rather than assigning to such pains the true but prosaic cause of irritation or inflammation of the œsophagus. Reflexes and sympatheticism have still a firm hold on our science, and a good many days will pass before these mythical expressions, synonyms of ignorance, will pass yonder, out of reach of lofty medicine. That ulcer of the œsophagus has not been detected every time it existed is due to the fact that the symptoms are so easily mistaken. The hemorrhages issuing from such ulcers and making their way to the external world through the mouth, are only too easily mistaken for pulmonary hemorrhages. In fact, my attention was called to the existence of an ulcer rather accidentally. Since the œsophagus lies almost entirely within the thorax, the usual symptoms, diagnostic of a pathological condition of any organ, are here, I might say nearly always, referred to the lungs, less frequently to the heart, and we are always sure to find something trouble—real or imaginary—with the lungs. The characteristic symptoms of ulcer are pain and hemorrhage. In ulcer of the œsophagus the first is complained of, and the latter is either not seen or misinterpreted. If the blood from such a hemorrhage of an œsophageal ulcer runs down into the stomach it is only too easily lost sight of, but if it comes up and is emptied through the mouth, the chances for misinterpretation are great indeed. The hemorrhage for which it is most likely taken is hemorrhage from the lungs, the mistake made in two of my own cases. A hemorrhage coming from an ulcer of the œsophagus is bright red. There is no reason why the blood from such an ulcer, which comes directly without first going into the stomach, should be any different than bright red in color and hence we can easily see the cause for mistake. The practical question is, How can we differentiate one from the other? The answer to this is, By the use of the stomach tube. Our procedure in a case of hemorrhage issuing from the mouth should be first symptomatic, that is, stop the hemorrhage, give the patient sufficient rest to recuperate, then after the lapse of a reasonable number of days attempt to make an absolutely positive diagnosis, holding in abeyance any positive assertions to the patient until such time. An absolutely positive diagnosis is not only of the greatest importance to the physician, but even more so to the patient. It is one thing for the patient to know that it was only an ulcer of the œsophagus, and it is quite another for an individual to believe himself to be consumptive. The high moral obligation of the physician in such cases is well understood by every practitioner. We certainly must not lose sight of the fact that outside of ulcers, the bursting of varicose veins in the œsophagus might claim its due share in the etiology of hemorrhages from the œsophagus.

In ulcer of the œsophagus, the stomach, tube causes irritation and consequent circular contraction of the œsophagus, for which reason the stomach tube cannot be passed. This irritative contraction of the œsophagus is also caused by the cicatrix after the healing of the ulcer. Of course, one must be sure of his dexterity in handling the stomach tube or the diagnosis of ulcer of the œsophagus will be made as often as one attempts to invade the sanctity of the gullet. To one who but occasionally uses the stomach tube an impossibility to propel the tube into the stomach must not always be construed as meaning a contraction of the œsophageal wall due to ulcer.

The differential diagnosis will be well appreciated when the physical examination of the lungs proves negative. But when there is a history of cough with expectoration, when râles are heard, and such a hemorrhage occurs, the duty of the physician is a hundred times augmented to be sure of the diagnosis. There is no reason why an ulcer of the œsophagus could not be present together with an innocent bronchitis. How easily can one be mistaken in such a contingency! Neither must the concurrence of a hemorrhage, coming through the mouth, with the presence of tubercle bacilli in the sputum, be looked upon as a hemorrhage necessarily coming from the lungs. Indeed, this very concurrence happened in my first case. The patient, a man forty-one years of age, coughed and expectorated, and the Board of Health, corroborating my own investigation, reported but very few bacilli found. The physical examination of the chest proved no consolidation or cavity, although plenty of râles, but the stomach tube elicited spastic contraction of the œsophagus, allowing the tube to progress only after a lapse of a half-minute or so. This spastic contraction happened both times when aspirating the fasting stomach, and when aspirating one hour after the test meal. The patient was a confirmed alcoholic, and the hemorrhages were due to alcoholic ulcer of the œsophagus. The patient came to me February 16, 1901. Four and a half months before he was seized with a hemorrhage while walking on the street. The hemorrhages repeated for four weeks, a little blood coming every day. Admits having had three or four whiskies a day, and quite a quantity of beer at each meal which usually was well spiced.

The history of the second case is: A woman forty-five years of age, with alcoholic past, visited me June 5, 1901, and gave the following history: Four weeks ago she had brought up clotted blood, accompanied by a dry, hacking cough. This lasted one day and passed off. Nine days ago she again was raising clotted blood for twenty-four hours. This was preceded by a burning sensation behind and along the sternum; diagnosis, ulcer of the œsophagus.

The third case was that of a woman, thirty-six years old, who had had nephritis and an abortion at the sixth week of pregnancy; she was moderately addicted to alcohol. The patient had excruciating burning pain, and pointed to the upper part of the manubrium sterni as the seat of her trouble. She could take nothing per os the first few days, even water gave her severe pain, for which reason she took none. Hemorrhages, bright red looking, came frequently the first few days, then less frequent. She died four weeks after complaining of the severe burning with her last breath.

The fourth case was that of a man, thirty-four years old, a fruit peddler, a native of Hungary. He was about 5 feet 7 inches tall, well built, strong, but not fat. He came to me December 11 last and complained of pain in the lumbosacral region. Especially was his pain pronounced on getting up from his seat, the bowels were hard. He complained of nothing else. Examination of his chest was negative. The abdominal examination was as follows: The right kidney was not felt, but the left was prolapsed in the first degree. The spleen was enlarged, extending above to the eighth rib and reaching one and a half inches below the free border of the ribs. There was slight resistance and slight evidence of pain at McBurney's point; the patellar reflexes were slightly exaggerated; the pupils responded to light and accommodation; the Romberg symptom was absent; the urine was negative. When I attempted to pass the tube into his fasting stomach, it encountered resistance soon after it passed the pharynx. The resistance lasted about a minute after which the tube proceeded into the stomach. The same occurred when I tried to aspirate the chyme one hour after the test meal. Prompted by this occurrence, I inquired for any possible previous condition referable to his chest, when the following history was elicited: Two years ago he had hemorrhages from his mouth which kept up for three days. He received the usual treatment in such cases and was subsequently sent to Colorado, where he stayed six months. Feeling better, he returned to New York. He had one other attack of hemorrhage since his return. Now, this patient was free from any lung trouble and the present healthy condition of his lung would certainly exclude a diseased condition having existed prior to his going to Colorado, or the cure there ought to be classed among the miraculous. His hemorrhages never came from his lungs, they came from an ulcer of the œsophagus. As to a probable cause, or at least a contributing cause, possibly the examination of his stomach contents may give us some clue. One hour after the test meal I aspirated 35 c.c. of chyme, coarse with some floury layer, and pungent odor. The microscopical examination showed short and long bacilli, curved bacilli, bead bacilli (mold), prismatic crystals (single sections of the oidium albicans) and gonidiæ. The chemical examination proved the case as one of organacidia gastrica, namely there was free HCl 24, organic acids 38 (presumably more), general acidity 82, no acid phosphates were present. This case had been treated as one of pulmonary tuberculosis of which there was no evidence. It was a case of ulcus œsophagi.

What a great consolation is it to the patient to know that he is not tuberculous, at least as far as his lungs are concerned! These four cases I have seen within a period of ten months. The fifth case was observed during a consultation. The patient had a dry cough and had had hemorrhages. He was seen in consultation by a prominent physician who could find nothing in the chest. Eight years ago the patient was treated by a well-known authority for stricture of the œsophagus, thus making the diagnosis of ulcer of the œsophagus more certain.

Backed by the experience of these cases, I believe I am justified in my assertion that ulcer of the œsophagus is a comparatively frequent disease; that the physician must be very careful before he pronounces a hemorrhage, bright red in appearance and issuing from the mouth, as a hemorrhage coming from the lungs; that the physician must never positively assume a hemorrhage to come from the lungs even if there are râles or other pulmonary symptoms, that in every case of such a hemorrhage the œsophagus must be very diligently searched by a competent man, and that the responsibility of the physician is much too great to allow of any laxity in the premises. That nasopharyngeal hemorrhages will be likewise kept in one's mind at such an occasion goes without saying.

136 East Seventy-eighth Street.

Creatinin Excretion.—D. L. Edsall made a series of observations on the urine in a case of family periodic paralysis to determine whether there was any evidence of acid intoxication. From a tabulated statement it appears that the creatinin excretion, which should normally be from 0.7 to 1.4 grams, was very greatly reduced, the amounts on several occasions being so extremely small as to be almost indeterminable. During the second attack, and immediately after the first and third attacks, the amount rose decidedly, the quantity found after the first and second attacks approaching the normal. The low figures in each instance preceded the onset of the attacks by several days, and the reduction in excretion was, therefore, not due to the attacks. The relation to the periods of paralysis was very striking. The prolonged period of freedom from paralysis between the second and third attacks, and the rise in creatinin excretion during this period seemed at first to show that in this instance, at least, the relation of the creatinin excretion to the attacks was not so close as the other figures would indicate. The author believes that the only conclusion justified by the results obtained is that there was a disturbance of metabolism in this disease, which preceded the attacks, and which ceased with the onset of the actual attack or directly after the attack; and it seems highly probable that this disturbance of metabolism was the cause of the onset of the attacks. Since creatinin is closely related to muscular metabolism, and its excretion showed the peculiar relation that it did to the attacks, and since the disease itself in its main clinical features was one affecting the muscles so prominently, it seems probable also that the essential feature in the disturbance of metabolism that apparently causes the attacks was an alteration in the chemical processes in the muscles themselves.—*Transactions of the Philadelphia Pathological Society.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 1, 1902.

THE SUBJECT OF EATING.

DISTINGUISHED authorities are as wide apart as the poles in their views as to what constitutes in quality and quantity a diet calculated to keep a person in sound health. Some declare—the most assertive among the number being Dr. Haig—that the only rational diet for a person is that which produces uric acid to the least extent. Others extol a wholly vegetable diet, while still others aver that without meat the individual is certain to lose vital energy, and to become listless, flaccid, and effeminate.

A writer of an editorial in the English *Polyclinic*, Jonathan Hutchinson's new journal, holds opinions by no means in harmony with those expressed by Sir William Thompson in his recent much-talked-of work on diet. The latter is a staunch believer in a vegetable diet.

The writer in the *Polyclinic* commences his article by quoting a saying of a Russian officer, and makes this the text for a dissertation on eating.

It appears that Captain Younghusband, a British army officer, came in contact with a certain commandant of a Siberian outpost.

The Russian colonel, by name Sokolowski, remarked to Captain Younghusband, "Je mange énormemént," at a dinner at which the Englishman was present. Six bottles of wine and beer were supplied to each guest, and course after course of the most substantial dishes were served up; yet, according to Captain Younghusband, the Russian officers, who lead a rough outdoor existence, were bursting with rude health.

Many eminent men have been abstemious to a degree, and just as many probably have been gourmands, and a not inconsiderable number have been wholly careless of what they eat or drink.

The *Polyclinic* editorial points out that Cardinal Manning was a typical ascetic; so much so, indeed, that Disraeli in "Lothair" puts into the mouth of one of his characters—supposed to be intended for the great Roman Catholic divine—on being pressed by his hostess to indulge in some of the good things proffered him, these words: "Thanks, your grace, I neither eat nor drink." Nevertheless, Manning far exceeded the span of life allotted to man.

Sir Andrew Clark was another conspicuous example of a small eater, who got through an immense amount of work; and history, both in America and the Old World, is thickly studded of great men who were gross feeders and heavy drinkers—witness Bismarck—and of those who partook of food but sparingly, and used alcohol not at all.

How, then, are we to reconcile these apparently glaringly, inconsistent facts?

The *Polyclinic* editorial in summing up the matter makes use of the following language:

"Speaking for those who enjoy good appetites and sound digestions, a large class among which, by systematic cultivation, the consumption of food might be much increased. Ought such cultivation to be encouraged or the reverse? No doubt but that many might retain health with a much more restricted allowance than they are accustomed to. Would they be the better for this restriction? How about the Weir Mitchell treatment and that adopted at Nordrach? At the latter place an attendant stands over the patient, and compels him to finish what is put before him.

"Are there many among those who account themselves healthy, who would become more secure from disease if some sort of compulsion of this kind were enforced upon them as a preventive measure? Do any dangers attend the habitual consumption of more food than is absolutely necessary, provided it be of good quality? Is mere excess in itself prejudicial, or does the overplus pass harmlessly away? The answer to these questions must, of course, depend much upon the habits of the individual. If great demands are to be made upon the system, whether physical or mental, then the supply should be liberal. It should also be varied. For anything we know to the contrary, it may be very desirable to supply to the tissues the elements of nutrition in varied forms.

"It may be that different tissues of the body exercise some sort of selection, as regards what they make use of for repair and waste. This may be of especial importance in reference to the nervous system. Small quantities of articles of diet, reputed to be only nervine stimulants, may possibly be real nutrients when not injudiciously used. That such an end should be served it is probably essential that they should be supplemented by plenty of ordinary food. Tea, coffee, and tobacco hurt no one who eats well, and the same is, with an added caution, true of wine."

The MEDICAL RECORD has always contended that it is impossible to lay down any hard and fast rule of eating or drinking for a body of people. The personal factor must be in every case taken into consideration—in truth, it commands the situation. What suits one person may be harmful to another, and if the individual be possessed of ordinary common sense, he will not be long before he finds out what food or drink agrees with him, and regulate his diet accordingly.

A dyspeptic who eats to excess, or partakes of food which disagrees with him, will, in the nature of things, suffer; and, if he be wise, will alter his mode of life.

There are, of course, diseases which are aggravated by an injudicious diet, and in such cases the physician's advice as to character and quantity of food should be strictly followed; but with the person in robust health, it would be unnecessary and even absurd to live by routine.

Change is the salt of life, and the aphorism may be applied with equal force to food. Persons who are slaves to their stomach will find in time that that organ is a hard master, and will regret that they ever put themselves under its rule.

In these days, fads dominate a large number of people to the exclusion of hard sense, all theories are ridden to death, and among them those concerning food and drink.

With regard to eating and drinking, the happy medium will be found the wisest course.

MOSQUITOS AND DENGUE.

"Insects as conveyers of disease," a phrase which, but a few years ago, would have carried little meaning to the scientist or medical man, and which, as a statement of fact, would have been pooh-poohed as the vision of an illusionary, is now looked upon as quite an ordinary assertion.

It is well known now that insects are a very important factor in disseminating disease, and it is recognized that their scope in this field has been much underestimated.

The classical studies of the English and Italian investigators, with regard to malaria and mosquitos, and the equally successful researches of the American army surgeons, in tracing the connection of low fever with the mosquito, have spurred scientific men everywhere to emulate these epoch-making discoveries.

In the Medical Record, February 8, Dr. Harris Graham, Professor of Pathology, American College, Beyrouth, Syria, contributes an exceptionally interesting article, in which he gives the results of investigations he has made concerning the part played by the mosquito in conveying dengue.

Dengue is a widespread disease, and the literature respecting it is consequently by no means scanty, but up to the time of the epidemic, which swept along the Syrian Coast in 1889, it was believed to be a purely miasmatic infection. Since the occurrence of this epidemic, however, many who have given the matter careful consideration, hold that it is essentially contagious.

The fact that dengue does not spread to any extent when carried away from certain low-lying lands struck Dr. Graham as being something more than a coincidence, and he determined to probe the matter.

His opportunity came in the late summer of 1901, when Beyrouth was visited by an epidemic of dengue.

Beyrouth is situated in a valley, is almost surrounded by mountains, and its vicinity is somewhat thickly covered with mulberry trees. Mosquitos, of the culex forms, are abundantly prevalent.

Dr. Graham's first experiments were in isolating well persons in rooms tenanted by those suffering from the disease, and from which mosquitos were entirely excluded.

The result of several such experiments, although in a sense negative, nevertheless showed that the dengue did not seem to be contagious, when mosquitos were carefully kept out of the house.

The next series of experiments undertaken were in direct inoculation, the disease was conveyed by the agency of infected mosquitos to three healthy young men, the fourth who allowed himself to be bitten, being apparently immune, having had a severe attack of dengue sometime previously.

In order to eliminate, as far as possible, all elements of chance, and to prove that contagion could not have come from any source otherwise than from mosquitos, some still more searching experiments were conducted by Dr. Graham, who would thus appear to be fully warranted in recording the following conclusions:

That the first class of experiments proves that, failing mosquitos, the dengue is not a contagious disease; and the second class evidences in direct inoculation that certain forms of culex may carry the disease from one person to another.

After having convinced himself that the mosquito was the means of conveying the disease, Dr. Graham proceeded to search for the cause in the blood of infected persons, and succeeded in discovering an amœboid form in certain of the red blood corpuscles, which was present in all the cases examined.

This parasite resembles, in many ways, the plasmodium malaria, but its cycle of production or formation in the human blood is so much longer than that of the malarial parasite that the changes in its life phase come more slowly and are more difficult to follow.

In Dr. Graham's original article the parasite is described at length, and several illustrations are given of the appearance it presents, viewed through a microscope.

At the end of his article the Beyrouth professor sums up his views as follows:

"It may not be absolutely proven that this hæmatozoon is the cause of dengue, but its constant presence in the red blood corpuscles during the fever, its resemblance to the parasite of the Texas cattle-fever, its likeness in manner of growth and mode of propagation (by the mosquito) to the malaria parasite, all point in the same direction, and lead us to believe, by analogy, if by no other way, that in this parasite we have the cause of dengue. The impression produced upon one's mind, after carefully reading Dr. Graham's paper, is that he has, indeed, discovered that mosquitos are—if not the only—at any rate a prominent agency in originating and disseminating the dengue.

In the light thrown upon malaria and yellow-fever by recent researches, this view is eminently reasonable and practical, and the negative and positive proofs brought forward by Dr. Graham in support of his theory are no less convincing than those furnished by the investigators of malaria and yellow fever.

No doubt further evidence must be forthcoming before the credit of the discovery is generally allowed to Dr. Graham, but his account seems so lucid, that difficulties need not be apprehended in this respect.

As to the value of the reputed discovery, it is impossible to hold two opinions, if it be finally confirmed by further investigations, then the course of procedure is plain, extirpate the mosquito and dengue will disappear.

Efforts to rid inhabited countries of the disease-bearing mosquito will doubtless be pursued with increased energy, as a result of the news from Beyrouth.

A REMARKABLE SANITARY VICTORY.

One of the most successful campaigns ever conducted by a military man is that recently waged in Havana by Major W. C. Gorgas of the Medical Corps of the U. S. Army. The enemy routed had been strongly intrenched in his fastness for one hundred and forty years, and his defeat has been marked by a great saving of life instead of loss of it. Yellow fever has been endemic in Havana since 1762, and for at least half a century hardly a month has passed without one or more deaths from the disease. Five months have now gone by without a single known case of yellow fever in the city. The argument in favor of the mosquito theory of the propagation of yellow fever drawn from the history of this campaign in Havana is a very strong one. It is thus stated by Major Gorgas in his report dated January [illegible] "1901 is the only year in which any attention has been paid to mosquitos in connection with yellow fever. In the two preceding years of American occupation, 1899 and 1900, every means known to science, and which money could command, backed by unlimited military authority, was used to destroy fomites on the theory that fomites were the means of propagating yellow fever. In 1901 the same efforts were directed to the destruction of mosquitos, on the theory that the mosquito is the only means of propagating this disease, and the hygiene of yellow fever was carried out from this point of view, the effort to destroy fomites having been entirely laid aside. These are the facts in the case, and I leave the department commander to draw his own conclusions therefrom."

In his next report, which has just been issued, he continues the argument. The figures show, he says, that the hygienic conditions in Havana in 1899 were better than ever before, yet there were three hundred and ten deaths from yellow fever in 1900. At the beginning of 1901 the prospects in regard to yellow fever were bad. There was a large non-immune population. Cases had occurred in all parts of the town. In January there were twenty-four cases and seven deaths, in February five deaths. Then Governor-General Wood determined that no precaution should be spared. He ordered that mosquitos should be destroyed, and this work was begun on the 1st of March. The decrease in yellow fever morbity began at once, although that was precisely the time when the number of cases and deaths would be expected normally to increase. It certainly is an argument which will tax the ingenuity of the opponents of the mosquito theory to overcome.

Co-operation of Railroads in Combating Smallpox.

Dr. Reynolds, the energetic and efficient Health Officer of Chicago, has recently enlisted the aid of the officers of the railways entering that city in his fight against smallpox. The incentive to this action was the discovery that in an area of 600,000 square miles around Chicago, with a population of about twenty-five millions, smallpox had increased over 900 per cent. in the past year. That is to say, between December 28, 1900, and January 24, 1901, there were only 1,070 smallpox cases reported in this territory, while during the similar period ended January 24, 1902, there were 10,820 cases reported—an increase of 911 per cent.

Dr. Reynolds, after a careful investigation, came to the conclusion that the situation was not being intelligently dealt with, and that a further spread of the disease, which seemed very probable, would not only prejudice public health, but also work injury to the commercial interests of the country by the eventual panic and institution of "shotgun quarantines." He therefore proposed to the representatives of the railroads centering in Chicago that concerted action be taken to stamp out the disease. The plan contemplated wholesale vaccination and revaccination in every infected locality; the provision and maintenance of suitable isolation hospitals where necessary, thorough disinfection of smallpox premises and belongings, strict inspection of all persons offering to travel from infected localities and refusal to carry those who do not comply with the requirements. Special attention will be paid to the condition of employees in manufacturing establishments—particularly those of textile fabrics—and the railways will set the example by still more rigorously making recent vaccination a condition of further employment. Competent vaccinators and supplies of pure, tested vaccine lymph will be furnished gratis in all proper cases. The work along such railway line will be under the direct charge of the medical director or chief surgeon of the company, and a central office will be maintained in the city for the receipt of reports, requisitions, etc., from those engaged in the campaign. Dr. Reynolds has volunteered to take charge of the central office. The plan has already been inaugurated by the vaccination of the railroad employees, and it is confidently hoped that the results of the concerted action of so many officials over such a large area of territory will soon be manifest in a lessening smallpox morbidity.

To Pension the Widow of Acting Assistant Surgeon Lazear.

The work in Cuba of the army yellow fever commission was recently brought officially before Congress in connection with the introduction of a bill to pension the widow of the late Contract Surgeon Jesse W. Lazear, U. S. Army, who died from yellow fever, communicated by the bite of an infected mosquito, to which, in the interests of humanity and medical science, he had voluntarily exposed himself. As contract surgeon, though sharing every peril equally with commissioned officers, are not entitled to benefit under the general pension laws, a special bill was introduced in the case of Dr. Lazear, and the Military Committee of the House agreed to recommend that a pension be granted his widow of seventeen dollars per month. This action is apparently all that a supposedly generous country proposes to take for the family of a man who freely offered up his life in the winning of one of the greatest discoveries of medical history; a discovery the money value of which to the United States alone—from the saving of life, the opening up of unrestricted traffic with yellow fever ports, the abolition of shotgun and other quarantines, and freedom from delay and costly disinfective processes—amounts to a sum computed only in hundreds of million dollars yearly. Dr. Lazear had a right to expect that his life sacrifice would not be passed over almost unnoticed, and that the country he hoped to benefit would ensure that his wife was at least spared the extremes of privation and want. The medical profession has reason to resent the grudging handing out of a seventeen-dollar-a-month pension as the value of self-sought martyrdom to the cause of humanity; particularly since not a Congressional session goes by without numerous private pension bills, each carrying several times the pittance regarded as quite sufficient in this case, being pushed through in favor of persons who have not a tithe of the just claim which Dr. Lazear's widow has upon the favorable consideration of Congress. Had Dr. Lazear fallen at the head of troops engaged in the destruction of life and property, many would have been eager to champion his cause and honor his memory as a hero; but it is unfortunately true that the work of saving life and relieving suffering is by the general public, slowly appreciated and soon forgotten. The unassuming heroism, self-sacrifice, and devotion of the physician, in his effort to improve the welfare and increase the happiness of his fellowmen, are more commonly belittled or ignored by the very persons for whose benefit he labored. Nothing that Congress could do would ever repay the widow of Dr. Lazear for the loss of the husband and breadwinner, but it was at least possible to have granted her a pension sufficient to procure the bare necessities of life. The failure of Congress to do this will not be regarded with approval by the medical profession of this country.

Dr. Lazear's case also calls attention to the fact that the surviving members of the yellow fever board, who shared with him the labor and peril of the work of investigation, and one of whom nearly succumbed to a self-inflicted yellow-fever infection subsequent to the death of Dr. Lazear, would, in any European country, have received reward, honors, and preferment at the hands of Government. That their work has been officially almost ignored proves the truth of the saying that republics are ungrateful, and illustrates the fact that in this country the only reward for the leaders in medical progress, who freely give their labors in the cause of humanity, consists in professional reputation and a consciousness of good work well performed. Still, we cannot but think that these are scarcely sufficient for such a tremendous benefaction to the human race as has resulted from the labors of the army yellow fever commission.

Proposed Detail of Surgeon General of the Army.

Senator Proctor has recently introduced a bill providing that hereafter the position of Surgeon General of the Army shall be filled by detail, for a period of four years, of a medical officer of the Army, who, at the conclusion of such period of detail or redetail, shall return to the position and grade in the Medical Corps which he would have held had he not been so detailed. Up to the present time, appointments to the position of Surgeon General of the Army have given a tenure of office during the remainder of the active service of the incumbent. The majority of medical officers are opposed to Senator Proctor's bill, believing that it not only diminishes the importance of the position and decreases its influence, but also will have a bad effect in a political sense. Up to the present time, the Surgeon General has been free to act for what he considered to be for the best interests of the Medical Department of the Army, entirely apart from political considerations, and there was no way by which his tenure of office could be jeopardized by a refusal to govern his actions according to political influences. The affairs of the Medical Department were, therefore, entirely outside the control of political meddlers. Should Senator Proctor's bill become a law, it would be a Surgeon General of most strong character who, in the future, as a candidate for reappointment, would not be more or less influenced by considerations as to the effect which his administrative acts would have upon the politicians, upon whose wishes the question of such reappointment would be largely decided by the President. With a four years' tour of duty, also, not only would it be difficult for the Surgeon General to outline any extended plan of improvement for the future with the expectation of seeing it accomplished, or to entertain a policy opposed to that of the Secretary of War, but he would scarcely be in a position to exact compliance with what appeared to him to be for the best interests of the service from medical officers, over whom he was temporarily in control, but under whom he might himself have to serve as a subordinate should he fail of reappointment as Surgeon General. For these reasons, Senator Proctor's bill, undoubtedly, pleases the politicians, but it does not at all appeal to those who have the interests of the Army Medical Department at heart.

Insurance Against Disease.

The population of Great Britain, and of London in particular, have during the past few years. developed an extraordinary propensity to insure against almost every possible untoward occurrence. This new custom can hardly be described as a fad, because the habit is largely dictated by sound common sense.

An immense sum of money was paid out by the large insurance companies upon the death of the Queen, and a very large number of policies, at a high premium, have been taken upon King Edward's life until the Coronation is past.

There has been—since the epidemic of smallpox in London assumed alarming proportions—a great rush to insure against the dangers to health and life which might accrue from contracting the disease.

The New York *Sun*, February 9, referring to the matter, says that insurance firms which usually sign only 80 to 100 policies a day have recently found their output average 600 policies.

The rate of insurance varies from half a crown (62 cents) per £100 ($500) for vaccinated persons, and 40 pence (80 cents) for unvaccinated persons to 15 shillings ($3.75) and 21 shillings ($5.25) per £100 ($500) for certain districts in the East End of London. Some insurance firms are sending circulars to their policy holders, offering to insure them against smallpox for 4 shillings ($1) per £100 ($500).

The British, notwithstanding reports to the contrary, still seem to be imbued with keen commercial instincts, and do not appear inclined to allow mere sentiment to overcome their inborn thrifty habits.

Although it is a novel departure to gamble against disease, the innovation has in its favor the fact that it is founded upon sound business principles.

Suicides in United States During 1901.

The Chicago *Tribune* a short time ago published an article commenting upon the statistics of violent deaths in this country in 1901.

Suicide of all forms of violent death shows the greatest increase. The total number for the year 1901 was 7,245, as compared with 6,755 in 1900, and 5,340 in 1899. Of this total 5 850 were males, and 1,395 females, which shows the same proportion of nearly five males to one female for several years past. Physicians head the list among professional men, the record standing: Physicians, 33; attorneys, 10; clergymen, 10; bankers, 6; journalists, 6; college professors, 1. The causes of self-murder were tabulated as follows: Despondency, 2,080; unknown, 1,643; insanity, 674; ill-health, 618, domestic infelicity, 541; liquor, 439; disappointed love, 283; business losses, 67.

Poison continues to be the most common agency in committing suicide; 3,106 killed themselves with poison; 2,476 by shooting; 614 by hanging; 513 by drowning; 356 by cutting their throats, and the remainder by various eccentric ways.

The statistics given above as to cause are but roughly drawn up; if a close analysis were made as to motives the results would be highly instructive from a psychological standpoint. The steady increase of the suicide habit is undoubtedly to some extent due to the ease with which poison may be procured. This fact is clearly demonstrated by the record of cases in a series of years commencing with 18[illegible], and adds a ghastly emphasis to the contention that the sale of poison should be much more strictly regulated than is at present the case.

LIQUOR REFORM IN RUSSIA.

Russia, when she undertakes any reform movement, uses no half-way measures. The radical methods of this immense empire, when it is deemed fitting to attack some question important to the welfare of the people or of the government, is rendered possible by the absolute power vested in the ruler of the country. The autocrat of all the Russias, when he wishes a thing done, but says the word and the vast political machinery is put in motion to effect his purpose. The public press and meetings are powerless, both, if considered troublesome, are suppressed. Accordingly the experiment initiated in Russia some time ago, to abolish saloons has been watched with great interest by temperance reformers in all countries.

The objects that the Government hoped to attain by taking control of the liquor traffic were:

(1.) To draw into its own treasury the profits derived from the manufacture and sale of intoxicants.

(2.) To substitute pure liquor for the adulterated and inferior compounds often sold by private dealers.

(3.) To break up the saloon habit, and lessen the temptation to drink by forcing consumers to carry their vodka home.

(4.) To discourage intemperance by opening teashops, people's houses, libraries, summer gardens and cheap theaters where the common people might find diversion and entertainment without liquor.

Mr. George Kennan, in *Outlook*, January 11, discusses the matter as to how far in practice these praiseworthy objects have been realized.

From a financial point of view, the reform has been successful, while in its attempt to substitute pure liquor of good quality for the chief and sophisticated stuff sold in the kabaks the Government has met with gratifying but not complete, success.

The attempt, however, to break up the saloon habit, and lessen the temptation to drink, by forcing customers to buy their vodka in sealed packages from the Government and take it home instead of drinking it on the premises, must be regarded, in Mr. Kennan's opinion, as a failure.

The result, from all reports, seems to have been a great and alarming increase of street drunkenness and disorder. The peasant buys his vodka and drinks it in the open street, the consequence being that there has been an immense increase of intoxication and riot in the streets, while the city hospitals are overcrowded, as an outcome of taking in peasants who have become ill from exposure to cold or rain from lying dead drunk out-of-doors.

The establishment by the Government of peoples' houses, libraries, reading rooms, etc., as substitutes for the closed kabaks, has been reasonably successful, and doubtless would have been more so, had it not been for the bureaucratic methods of management. Officialism is so rampant in Russia, that the control of the above-mentioned institutions has been placed in the hands of Government officials whose only thoughts are to feather their own nests.

The Russian medical journal, *Sputnik Zdarovia*, sums up the whole question concisely and well when it says: "If the Russian peasant is to be prevented from drowning thought and memory in the lethal flood of drink, he must first be made strong and healthy; he must be raised physically and mentally, to a higher level, the material and economic conditions of his life must be improved; his earnings must be increased, and he must be relieved from a chronic state of famine."

Nevertheless, it must not be forgotten that the experiment in Russia has not yet been tried sufficiently long to pass any definite opinion with regard to its success or otherwise.

The drink question is one that is alarming far-seeing men in every country of the world, and it is the strong opinion of such that vigorous steps must be taken to diminish the evil effects of alcohol.

Therefore, Russia has set a good example to nations who regard themselves on a far higher plane of civilization than the colossus of the north.

EXAMINATION FOR CANDIDATES FOR ASSISTANT SURGEON, U. S. A.

The examination of candidates for appointment as assistant surgeons in the army will be resumed by the Army Medical Examining Board in Washington, on Monday, April 7 next, and will continue so long as there are applicants to be examined. There are now sixty-three vacancies in the Medical Corps with the certainty of three more from retirements for age and probably an additional number from casualty, in the early future. It is understood that at present there are less than fifty applications for examination on file at the War Department. From figures given in the report of the Surgeon General for 1901, based upon the number of appointments made from the applications received during the previous decade, it cannot be anticipated that more than six or seven of the present applicants will be found qualified by the examining board, and will be recommended for appointment, so that after the examination of every medical man who can be induced to present himself before the coming examining board there will probably still exist about sixty vacancies in the Medical Corps, or a number equal to about 20 per cent. of its entire authorized strength.

Prior to the passage of the army reorganization act in February, 1901, the Army Medical Corps always had an abundance of well-qualified candidates for commissions from which to make selection. As has already been stated in these columns, present deplorable conditions are directly due to the provisions of the army reorganization act above referred to, by which the status of the medical officer was so degraded, when compared with previously existing conditions of rank, pay, and promotion, enjoyed for many years, as to destroy the attractiveness of the military service to young medical men of the character and qualifications desired. Even with several hundred medical officers of volunteers and contract surgeons now serving with troops, and presumably finding a military life congenial, very few are apparently willing to enter the regular service with a view of making it their life work, with its present unpromising outlook as to pay and promotion. The class of men which the Army Medical Corps desires cannot be secured by the emoluments for continued service offered under the law of February, 1901; and many young physicians who are attracted by the Government service are turning away from the army to enter the Medical Department of the Navy or Marine Hospital, where as they grow older in the service, they will receive much more in the way of pay and allowances than they could hope to obtain by an equal period in the army. Under present conditions, it cannot be disguised that the outlook for the future efficiency of the Army Medical Department is highly unpromising. The situation is one which calls for the earnest consideration of the profession and its active interest in the institution of measures for relief.

American Naval Sailors and Their Right to Refuse Minor Operations.

The Navy Department, by Acting Secretary Darling, has recently decided that an enlisted man in the Navy or Marine Corps has no right to refuse to submit to a surgical operation, if it be not serious, but declines to lay down any rule for cases involving the loss of a limb, or in which a man's life might be endangered.

The Secretary recommends the exercise of persuasion and diplomacy on the patient in serious cases, but in minor cases he decides that the man who refuses to be operated upon is guilty of disobedience to orders, and may be court-martialed and punished.

The case recently decided by the Acting Secretary was that of a marine private, serving on the *Monadnock* in Chinese waters. The ship's surgeon wished to remove a foreign growth which unfitted the marine for duty, but failed to gain his consent to the operation. The recalcitrant marine was reported to Rear-Admiral Louis Kempff, who took the patient's stand and refused to allow the surgeon to operate. An appeal was then taken to the Navy Department, when the Bureau of Medicine and Surgery gave out as its opinion that most cases of this description could be adjusted by the use of tact and persuasion in attempting to induce the patient to submit to an operation, but held that when a minor operation only was necessary, the patient should be required to submit or be punished. Acting Secretary Darling upholds these views.

Admiral Kempff was right in refusing to allow the marine to be operated upon against his will, and in championing the cause of the enlisted man to exercise his inalienable birthright of free will. Undoubtedly, in perhaps the great majority of such cases the surgeon is the best judge as to whether an operation would be beneficial or not, and the patient would be wiser to leave the matter to his discretion, but although, of course, discipline must be maintained, the principle must not be carried to the point of not permitting a man to be the master of his own body.

Sanitary Matters in Cuba.

General Leonard Wood. the military governor of Cuba, has recently authorized the establishment of schools for nurses, in connection with Cuban hospitals, having power to issue diplomas to graduates showing fitness for the practice of their profession. These training schools are classed as State institutions, and will be under the immediate supervision of the department of charities. In the order establishing these schools it is stated that their purpose is, first, to further the best interests of the nursing profession by establishing and maintaining a universal standard for instruction, and providing students with the proper means of education in the practical care of the sick; second, to secure for students, upon graduation, a degree or title which will be a protection in practising their profession, and be a recognized means of securing employment, third, to provide hospitals and institutions in the island with skilled service in the nursing department and a proper number of graded assistants, "thus conferring a benefit to the mass of suffering humanity."

The professional training of General Wood, with his long experience as a medical officer of the army, has rendered him particularly interested in matters of a medical nature, and has stood him in good stead in dealing with Cuban sanitary problems—which have been certainly not the least in importance among those arising during the work of reconstruction, and which have been solved by him with such conspicuous ability and success. It was, undoubtedly, the presence of General Wood as the executive head of affairs in Cuba which rendered possible the brilliant results obtained by the commission of army medical officers appointed to investigate into the causes and prevention of yellow fever—results which could scarcely have been obtained under a less broad-minded and scientifically appreciative administration. In the consideration of the results obtained by this commission, the fact that it received the steadfast moral and official support of General Wood, and was enabled to carry on its experiments to a successful conclusion because of the generous appropriations made by him from the insular funds of Cuba, should always be given their share of credit. It is, undoubtedly, a fact that General Wood has been particularly fortunate in meeting with opportunity, and in having his professional knowledge fortified by unlimited executive powers, but it is none the less true that, with the evacuation of Cuba by our troops in May next, he will have done more toward the general sanitary well-being of a people than has ever been accomplished by any other medical man, whatever his name or generation. His successes will form an unfading chapter in the achievements of American medicine, to which, rather than to the military service, they must be attributed.

The Banana as a Food.

A writer in the current number of *Longman's Magazine* waxes enthusiastic over the possibilities of the banana as a food, and suggests that those living in temperate climes should avail themselves of its nutritive properties.

The banana is to the dwellers in tropical lands, and especially to the South Sea Islanders, what oatmeal is to the Scotch peasant. The contributor to *Longman's* states that the banana as a form of nourishment can claim first place among vegetable products that are food for mankind, for it is twenty-five times as nutritive as the ordinary white bread eaten in this country, and forty-five times as nutritive as the potato.

Moreover, it satisfies that other essential condition of a breadstuff—namely, the possibility of an easy and abundant production.

The suggestion of its advocate is that the banana, like wheat, should be dried and ground down into flour. Mills might be erected where it is grown, or within easy reach, and then, at the suitable time, the fruit could be gathered and dried, and transformed into flour. Banana bread has been voted excellent, is now made in Chicago, and might just as well be made in any other place, could the flour be obtained reasonably.

There would seem every reason in favor of the banana fruit being widely utilized as a food. In these days, when pessimists and even scientific men are warning us that the world's supply of wheat may in the not far distant future become insufficient, the act would be a wise one to cultivate and to procure the nutritive breadstuff which the banana so bountifully provides.

A New Local Anæsthetic.

The *Lancet* in a recent number writes of a new local anæsthetic procured from a plant named "gasu-basu," a native of India, the active principle of which is an alkaloid. The English journal says that experiments were made with a salt obtained by treating the alkaloid with hydrochloric acid. The salt has been named nervocidine. In weak solutions it produced a marked local anæsthesia of the cornea of warm-

[illegible] 1 per cent. solution applied to the human conjunctiva produced a burning irritation accompanied by lachrymation, and followed after twenty minutes by anæsthesia of the cornea lasting for five hours. After seven hours the cornea regained its normal condition. A 1-25 per cent. solution of nervocidine brushed over the mucous membrane of the pharynx caused local anæsthesia of the brushed surface, and of the tongue, accompanied by loss of the sensation of taste and the perception of touch, but without loss of the conception of heat and cold. Subcutaneous injections of the drug have not as yet been successful in producing local anæsthesia in animals. The general action of nervocidine on the system was that of a toxin which, by paralyzing the motor centers of the nervous system and of the peripheric nerves, caused death. All the experiments up to the present undertaken proved that nervocidine was a powerful local anæsthetic possessing a great advantage over cocaine in that it produced a much more sustained action, for the effect of a ⅕ or 1-5 per cent. solution might last for two or three days. The new anæsthetic, however, has its drawbacks, such as the local irritation to which it gives rise, the slow production of a state of anæsthesia (from ten to twenty minutes being required), and a liability to cause nausea, vomiting, salivation, and other symptoms of general poisoning.

A local anæsthetic whose properties last for such a length of time as that described above might be of the utmost value to surgeons and especially to ophthalmologists. There can be no doubt that more will be heard of nervocidine, when it will be easier to pass a competent judgment upon it.

Pathological Society of Philadelphia.—At a stated meeting held February 13, Dr. W. M. L. Coplin made an "Exhibition of Tube-casts Showing the Microchemic Reactions for Mucin, Fat, and Histologic Elements." Among the stains used were muchematein, Sudan III, and safranin. Dr. M. Howard Fussell exhibited a specimen of "Primary Carcinoma of the Head of the Pancreas with Gall-stones." The patient was a woman fifty-three years old, who had made no complaint and had never exhibited jaundice until within a short time before death, which followed operation for the relief of evacuation of fluid that had been detected in the abdominal cavity. In addition to the neoplasm of the pancreas and a large number of calculi in the gall-bladder the cystic duct was found occluded by stones, and evidences of peritonitis were present. Dr. Joseph McFarland reported "A Case of Bothriocephalus Latus" in a young Russian who at long intervals during a period of many years passed large segments, although never able to secure expulsion of the head of the parasite. He did not exhibit the characteristic anæmia. Dr. Robert N. Willson also referred to a case of like parasitism occurring in a Russian woman, who too passed long segments, and from whom after much treatment the head was expelled at the hands of an irregular practitioner. Dr. J. F. Schamberg presented "A Report of an Autopsy on a Leper, with Exhibition of Specimens." The patient had been a native white woman, seventy-three years old, who was not known ever to have been exposed to the risk of infection with leprosy. The lesions were of the tubercular type, without anæsthesia, but there was a chloasma-like area on the right temporal region. Death resulted from uræmia, and histologic and bacteriologic examination disclosed typical lesions and bacilli of leprosy. Dr. Ellis E. W. Given exhibited "An Exencephalic Monster with Bilateral Harelip and Cleft Palate."

News of the Week.

Volunteer Surgeons in the Phillippines.—The Secretary of War has requested that Congress continue in service for an additional year, until June 30, 1903, the fifty surgeons of volunteers with the rank of major, and the one hundred and fifty assistant surgeons of volunteers with the rank of captain authorized for duty in the Philippine Islands.

American Laryngological and Otological Society.—A meeting of the Eastern section of this society will be held at the New York Academy of Medicine, 17 West Forty-third Street, on Saturday, March 1, 1902, at 11 o'clock A.M.

Recovery of Dr. Charles H. May.—The many friends of Dr. Charles H. May will be glad to learn that he has fully recovered from his recent severe illness, and that he has resumed practice.

Banquet in Honor of Dr. Gregory.—The medical profession of St. Louis, under the auspices of the St. Louis Medical Society, will give a testimonial banquet to Dr. E. H. Gregory, who for fifty years has been an active teacher of medicine, probably longer than any other man living. The banquet will be held at the Planters House Thursday evening, April 17. A large number of guests will be invited, including all the ex-presidents of the American Medical Association, out of compliment to Dr. Gregory, who was president of the Association in 1887. A committee, composed of Drs. F. J. Lutz, N. B. Carson, C. H. Hughes, J. P. Bryson, W. B. Outten, and H. W. Loeb, has the matter in charge.

Philadelphia County Medical Society, North Branch.—At a stated meeting, held February 26, Mr. John W. Hill, consulting engineer of the Water Department of Philadelphia, presented a communication on the "Results of a Year's Experience with the Filtration of Philadelphia's Water." He pointed out that Philadelphia has at present about the worst water supply with reference to sewage contamination of any large city of the world. The experimental results have shown, however, that it will be possible by means of the filtration plant that is in progress of construction, and it is expected will be completed in the course of two and a half years, to provide a clear and pure water supply, and thereby bring about a great reduction in the amount of disease and in the number of deaths due to the use of contaminated water.

The Late Professor Paul F. Munde.—At a regular meeting of the Alumni Association of Mt. Sinai Hospital the following minute was entered:

"Death has taken our beloved teacher, friend, and helper, Dr. Paul F. Munde, in the fulness of his fame and power. His universal kindness, his never-failing courtesy, his generosity, and, above all, his loyalty, rendered him dear to every member of the Mount Sinai Alumni Association. We shall never forget the lessons learned at his hand and enforced by his precept. We are better physicians and better men for having lived in close contact with him. In the sorrow that we personally feel, we extend to the family our sympathy most heartfelt and sincere, realizing, however, that it is impossible 'to gild a grief with words.'"

Dr. Samuel M. Brickner, Dr. Albert A. Berg, Dr. Charles Goodman, Dr. Martin M. Ware, Committee.

Yellow Fever Quarantine.—The Sanitary Congress just held in Havana has accepted in its entirety the mosquito theory of the spread of yellow fever. Resolutions were offered that efficient prophylaxis consists in the destruction of all infected specimens of *Stegomyia fasciata*, and that quarantine regulations should be established in accord with this doctrine. The latter clause was, however, rejected as a result of the protests of representations from the Gulf States, who are almost unanimous in their refusal to regard the mosquito as the sole conveyor of the yellow-fever poison. Dr. Porter of Florida was one of the most urgent opponents of the quarantine resolution, and supported his arguments with those of Dr. Suchon recently published in the Medical Record. Among the members of the Congress were delegates from the United States, Mexico, Costa Rica, Uruguay, Paraguay, Nicaragua, Colombia, Santo Domingo, Argentine, and Cuba.

The New York State Hospitals.—The ninth annual report of the State Charities Aid Association was issued a few days ago. The publication consists largely of reports from the thirty-five visitors of the association on the eleven State hospitals. The visitors are practically unanimous in stating that the State hospitals for the insane have been well managed by the boards of managers lately legislated out of existence. While they praise the conduct of the hospitals, they criticize the congestion of the institutions, the report stating that each hospital is at present accommodating from 100 to 500 more patients than it has room for. The opinion is expressed that reduction in the expense of maintaining the insane has already reached a minimum, the average per capita cost for the year ending October 1 being forty-six cents a day.

The Battle Creek, Mich., Sanitarium was seriously injured by fire on February 18, the main building and the hospital being destroyed. Although there were many patients in the institution and the fire occurred very early in the morning, no lives were lost.

The Mt. Sinai Alumni Association.—The regular annual dinner and reunion of the Association of the Alumni of Mt. Sinai Hospital was held at the "Arena" in this city on February 14, Dr. E. J. Ware presiding, and among those who delivered addresses were Mr. Isaac Wallach, president of Mt. Sinai Hospital; Drs. A. Jacobi, A. G. Gerster, E. Gruening, A. Meyer, B. Sachs, and Mr. L. Wiley.

The following officers were unanimously elected for the ensuing year: *President*, Dr. Samuel M. Brickner; *Vice-president*, Dr. Albert A. Berg; *Secretary*, Dr. Charles Goodman; *Treasurer*, Dr. Martin W. Ware.

Dr. Tryon and Sailors' Snug Harbor.—On February 16 Drs. Kinnicutt, Janeway, Bryant, Andrew H. Smith, and Derby, of the Consulting Board of the Sailors' Snug Harbor, visited Staten Island and inspected the improvements made by Dr. Tryon in the sanitary and medical conditions of the institution.

Acting with the hearty co-operation of Governor Delehanty, Dr. Tryon has introduced an admirable system of registration and record of all inmates of the Snug Harbor. The wards of the hospital have been renovated; everywhere the most modern plumbing has been introduced, and the institution stands to-day a model for other nations to copy. A new surgical operating room is yet to be built, and the trustees of the Harbor are to be congratulated that in all the changes that have been made, they have enjoyed the wise direction of Admiral Tryon.

The Harvard Medical School.—It was announced a week ago that there remained but $200,000 to be raised in order to fulfil the condition necessary to secure the $1,000,000 gift from Mr. Rockefeller. Among the contributions recently received is one of $100,000 from Mr. James Stillman of this city, which will endow a new professorship of comparative anatomy. Another gift of $75,000 will be used to endow a clinical professorship of some subject not yet announced.

Quarantine for the Unvaccinated.—A vaccination bill, which was recently reported favorably in the New York State Senate, increases the powers of the local health authorities and allows a local Board of Health to quarantine for fourteen days a person who refuses to be vaccinated.

Civil-Service Examinations for the Pathological Institute.—Examinations will be held in this city on March 15 of candidates for the following positions on the staff of the Pathological Institute: Associate in chemistry, salary, $1,800; associate in clinical psychiatry, salary, $1,200; chief associate in neuropathology, salary, $1,800.

Cadavers Saved from Fire.—During a fire in a hospital attached to a medical school in Chicago recently, the firemen, who groped their way through the dense smoke, heroically carried out six dead bodies. The bodies had just been received for dissection, and were lying partly clothed, on the floor, and the firemen thought they were patients or attendants who had been asphyxiated by the smoke and gas.

Strike of Medical Students.—Nine medical students at the University of Iowa were recently suspended for disorderly conduct, and eighty-three of their sympathizing classmates have gone on a strike and threaten to leave the college unless the suspended men are reinstated.

A Worsted Anti.—A stubborn antivaccinationist in Boston was recently saved in spite of himself. He refused to submit to vaccination and was accordingly fined five dollars; then he refused to pay the fine and was sent to jail for ten days. As soon as he was locked up, the jail physician vaccinated him, as the law authorizes the health authorities to vaccinate prisoners whether they like it or not. And so this "conscientious objector," as the antivaccinationists are euphemistically called in England, was well vaccinated, but still had ten days to stay in jail for refusing to be vaccinated. It is to be hoped the victim has a sense of humor to alleviate the pains of martyrdom.

A Jewish Hospital in Brooklyn.—A meeting was recently held in Brooklyn to advocate the erection of a hospital for Hebrews in that borough. The call for the meeting was issued by the Jewish Hospital Society, and several thousand dollars were pledged to the building fund. It is proposed to raise $100,000 before starting building operations.

Lawyer and Doctor.—Dr. William Oliver Moore of this city was admitted to the bar as an attorney and counsellor at law of the State of New York on the 17th inst. He expects to continue his medical practice, and at the same time interest himself in medicolegal matters.

Harlem Hospital, New York.—Dr. Herman Jarecky has been appointed Visiting Otologist to the Harlem Hospital.

Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases.—Dr. S. Weir Mitchell has resigned the position of visiting physician, which he had held for thirty years, and has been elected Consulting Physician. Dr. John Madison Taylor has resigned the position of Assistant Physician, which he had held for twenty years. Dr. John K. Mitchell, formerly Assistant Physician, has been elected Visiting Physician in succession to Dr. Weir Mitchell.

Dr. Roswell Park, on February 19, delivered an address on "University Life in Medieval Times" before the Charles K. Mills Neurological Society and the University of Pennsylvania Medical Society and was afterward tendered a reception.

Philadelphia Polyclinic and College for Graduates in Medicine.—Dr. David D. Stewart has resigned as Professor of Diseases of the Stomach and Intestines, and Dr. Joseph Sailer has been elected his successor.

Chicago Academy of Medicine.—At its annual meeting, February 14, 1902, Drs. W. L. Baum, W. A. Evans, J. G. Kiernan, H. N. Moyer, and E. S. Talbot were elected directors. Dr. W. L. Baum was elected president of the directors and Dr. J. G. Kiernan secretary, who thereby becomes secretary and treasurer of the Academy.

Dr. Russell's Disclaimer.—Dr. James Edwin Russell, of 1032 Bedford avenue, Brooklyn, N. Y., asks us to publish the following: "Dr. Russell regrets the necessity that compels him to refute recent newspaper statements associating his name with certain preposterous propositions, and desires to inform his friends, clientele, and colleagues that he brands the same absolutely and unqualifiedly false—the only foundation, in fact, for the sensational publications being a private letter under a nom de plume in reply to one addressed to the correspondence department of the Brooklyn *Daily Eagle*."

University of Pennsylvania.—A contract has been entered into by the Trustees of the University of Pennsylvania for the erection, at a cost, including equipment, of $600,000, on the south side of Hamilton Walk, of new medical laboratories which it is intended shall be the largest and most complete in the United States. The laboratories will occupy the site of the present buildings of the veterinary department, which are soon to be razed. The style of architecture of the structure will be Jacobean, matching in outline features the dormitory structures, which are close by. The building will have a length of 340 feet and an extreme depth of 245 feet. Half way between the eastern and western ends, at the rear, a hexagonal structure will be erected containing two amphitheatres, each with a seating capacity of 400 persons. The building will be two stories in height and fireproof. It will be admirably supplied with natural light. The front of the building will be devoted to small rooms for special medical work and special research. At each end of the main building will be a demonstration room with a seating capacity of about 200.

Philadelphia Pediatric Society.—At a stated meeting held February 11, 1902, Dr. J. H. W. Rhein exhibited a case of "spasmodic tic in a child two years old." Some weeks following a mild attack of diphtheria twitching of some of the muscles of one side of the face developed. Examination disclosed a tight prepuce, removal of which was followed by disappearance of the twitching. Dr. E. H. Siter exhibited "A Case of Tuberculous Peritonitis; Operation with Recovery." The patient was a girl of about nine, who presented symptoms of appendicitis for the relief of which she was operated upon. Peritoneal tuberculosis with effusion was found, and after thorough exposure to air and light the abdominal cavity was irrigated and closed. Dr. Charles W. Burr exhibited "a case of idiopathic muscular Atrophy." The disease was of the pseudo-hypertrophic type, and occurred in a boy about seven years old. The calves were enlarged and indurated, while the remainder of the body generally was emaciated. The progress of the disorder was unusually rapid. A brother suffered from a similar disorder. Dr. Burr exhibited also "a case of spina bifida." The patient was a girl twelve years old, whose antecedent history was not known, but who presented teeth characteristic of congenital syphilis. The lower extremities were paralyzed, and the reflexes in these parts were exaggerated, and control of the sphincters was wanting. A large tumor was present in the sacral region, yielding a sense of true fluctuation, together with resistance of a solid body. Dr. Alfred Stengel presented a communication entitled "Rheumatism in Childhood." He pointed out the tendency to recurrence on the part of rheumatism in early life, its greater resistance to salicylates than in adult life, and the more character of the general as distinguished from the local symptoms, the endocardium and the pericardium suffering more commonly than the joints. He referred also to the occurrence of rheumatoid arthritis in early life. Dr. J. F. Schamberg read a paper entitled "An Outbreak of Chicken-pox Among Convalescents from Smallpox, with Remarks upon the Relationship of the Two Diseases." He showed that the overwhelming consensus of opinion was in favor of the duality of the diseases, and that the conception of their identity was based upon either unfamiliarity with chicken-pox or some fault in observation.

The Brooklyn Medical Society.—At the annual meeting of this society, held in January, the following officers were elected: *President*, Dr. William H. Haynes; *Vice-President*, Dr. Malcolm E. Parrott; *Recording Secretary*, Dr. Hugh Rogers; *Corresponding Secretary*, Dr. Alfred Bell; *Treasurer*, Dr. Albert H. Brundage; *Librarian*, Dr. Lewis E. Meeker.

An Isolation Hospital in Greenwich.—Mr. Robert M. Bruce, of Greenwich, Conn., is to build a hospital for infectious diseases which, when completed, he will present to the town. The hospital will consist of a number of separate one-story pavilions on a fifteen-acre plot of ground.

Generous Bequests.—By the will of the late J. Alfred Kay, a law-book publisher of Philadelphia, residuary bequests are made as follows: Pennsylvania Hospital, Germantown Hospital, University Hospital, Jefferson Hospital, Orthopedic Hospital, Polyclinic Hospital, $5,000 each, for the endowment of free beds; St. Agnes' Hospital, St. Joseph's Hospital, Jewish Hospital, Hahnemann Hospital, Presbyterian Hospital, Philadelphia Dispensary, German Hospital, Gynecean Hospital, Howard Hospital, Medico-Chirurgical Hospital, Children's Hospital, $1,000 each.

The William Pepper Society of the Medical Department of the University of Pennsylvania held its annual dinner on February 13. Speeches were made by Drs. Alfred Hengel, Charles K. Mills, DeForest Willard, Alexander C. Abbott and Hobart A. Hare.

Modification of Smallpox Quarantine in Philadelphia.—On the recommendation of a commission of five medical experts, the Department of Public Safety of the City of Philadelphia, houses from which patients suffering from smallpox are removed to the Municipal Hospital, will be quarantined only for a length of time sufficient to practise thorough fumigation and vaccination or revaccination of the other inmates. If the patient be not removed to the Municipal Hospital, quarantine of five or six weeks will be maintained. Other inmates of the house will be released from quarantine on being vaccinated or revaccinated, or presenting satisfactory evidence of recent successful vaccination.

The Philadelphia Neurological Society.—A stated meeting will be held in the Hall of the College of Physicians of Philadelphia on Tuesday, February 25th, 1902, at 8:15 P. M.

Dr. Adolf Meyer, Director of the Pathological Institute for the New York State Hospitals, will, by invitation, deliver an address entitled "Conditions for Psychiatric Research." Members of the profession are cordially invited to attend. After the address a reception will be tendered Dr. Meyer at the University Club.

Jefferson Hospital to Be Rebuilt.—Plans have been completed for erecting on the site of the old college building, now used as an annex, a new hospital for Jefferson Medical College. The new structure will harmonize with the new college building, and it will be seven stories in height. It will contain the J. M. Daleosta Clinical Laboratory and Amphitheatre, a gift to the college from its alumni and friends of the late Dr. DeCosta. The capacity of the new hospital will be 275 beds as compared with 125 in the old. The old building will be replaced by a new maternity and nurses' home.

Dr. J. A. Baird of Dunlo, Pa., in an effort to save two women from death, slipped on the rails and fell, and was run over by the cars and killed. He was fifty-two years old.

Professor W. O. Atwater of Wesleyan University, the food and dietary expert, has been summoned to Havana for conference with Cuban officials relative to the dietary standards to be required in the rations allowed to public institutions, under the Board of Charities now being organized by the newly-elected Cuban Government.

Gifts to Hospitals.—Mrs. J. H. Burtis has offered to the Memorial Hospital for Women and Children $5,000 on condition that the existing debt of $15,000 be paid off. Mrs. H. N. L. Sherman has given $25,000 to the Post-Graduate Hospital for the establishment of a ward for women and children suffering from nervous diseases. The ward is to contain fourteen beds, five of which will be supported in perpetuity by this gift. The new ward will be called the Hope Ward.

Obituary Notes.—Dr. Levi Cooper Lane died at his home in San Francisco on February 19, at the age of sixty-nine years. He was a graduate in arts of Union College, Schenectady, N. Y., and in medicine of the Jefferson Medical College, Philadelphia, in 1851. He spent some time in post-graduate medical study abroad, obtaining membership in the Royal College of Surgeons, and had lived and practised many years in San Francisco. He was prominently identified with the cause of medical education in his adopted city, having been connected with Cooper Medical College and the Lane Hospital. For several years past an annual course of lectures founded by him, called the Lane Lectures, has been delivered at the Cooper Medical College by well-known British medical men.

Dr. George Zabriskie Hunter died at Glen Ellen, Cal., on February 16, at the age of fifty-four years. He was born in this city in 1848 and was graduated from the New York University Medical School in 1872. He served as surgeon several years on steamers of the Pacific Mail Line, but gave up sea life when he began to suffer from rheumatism and took up his residence in California.

Dr. Louis Lewis of Philadelphia died at St. Vincent's Hospital in this city on February 18, after an operation at the age of sixty-three years. He was born in England and received his license to practice from the University of London and the Royal College of Surgeons. He served for a time on the medical staff of the British Army, but left the service and came to this country in 1883. He was at various times editor of the *Medical World*, the *Medical Council*, and the *Medical Times and Register*.

Dr. Halpern Albert, a dentist of this city, died on February 18, at the age of seventy years. He was born in Paris, but came to this country at the age of twenty years.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING F.R.C.P.—THE PRINCE F.R.S.—PARLIAMENTARY—THE EPIDEMIC—DEBATE ON VACCINATION—OBESITY—THE NEW DIRECTOR GENERAL A. M. S.—OBITUARY.

London, February 7, 1902.

The King has consented to remain a Fellow of the Royal College of Physicians.

The Prince of Wales attended the meeting of the Royal Society on Thursday, and was formally admitted to the Fellowship, to which he was elected in 1893. His qualification is being a Prince of the Blood Royal. Having signed the roll immediately under the signature of his father, the King, His Royal Highness listened to a lecture by Sir Wm. Crookes on the "Stratification of Hydrogen: Radioactivity and the Electro Theory," and to observations by Lords Kelvin and Rayleigh.

The Prince then expressed pleasure at admission, and said that, as elected eight years ago, he really ought to apologize for not having attended sooner. But he was proud to add his name "to those on your illustrious roll, which has been inscribed by nearly every sovereign since the reign of Charles II., and by all the most illustrious men of science since—such, I may mention, as Wren, Newton, Davy, Faraday, Darwin, and many others." He then thanked Sir Wm. Crookes for his interesting lecture, and congratulated him "on his power of treating such an abstruse subject—for I must say that the title rather alarmed me [laughter]—so as to make it enjoyable and attractive to those who, like myself, unfortunately cannot lay claim to much scientific knowledge. But while fully recognizing how far beyond my reach this knowledge lies, I can assure you of my hearty sympathy with that scientific study and research which now, more than ever, has become so important and essential in our national life."

You may be sure the speech was received with hearty applause, and that a very large number of Fellows were present to hear it.

In Parliament there have been a number of questions asked which more or less concern medical matters. One of these referred to the Medical Council's action in Dr. Randall's case. The reply given was that the Act defined the Council's powers, and the Government had no need to consult the law officers about it. The papers which had tried to get up a cry that "the poor man's doctor" was to be eliminated by the Council have done Dr. Randall an ill turn.

Our trouble with smallpox does not diminish. Yesterday it was aggravated by invasion from your side. The steamship *Kansas*, from Boston, brought eighteen cases to Liverpool. They were taken to the isolation hospital. The vessel, a large cattle boat of the Warren Line, is being disinfected, and other measures taken by the active sanitary authorities of Liverpool. Some other American cattlemen have developed the disease in a lodging house, and the inmates have been promptly isolated.

In London the epidemic has continued with the usual variations from day to day. This day week the notifications numbered eighty-two. They have varied since from seventy-five on Saturday to twenty-seven yesterday. There are between 1,100 and 1,200 cases now in the hospitals. Many are confluent, and, of course, there are frequent deaths. The remote position renders the supplies an arduous undertaking. One day a difficulty was reported in respect to funeral arrangements, but it was afterward stated that everything was well managed.

The discussion on modern methods of vaccination, which was begun at the Medico-Chirurgical Society, in December, and referred to in my letter of the 14th of that month, has at length been concluded. A debate carried on for three evenings, at intervals of two and four weeks, by speakers announced in advance, is naturally devoid of the spontaneity expected in discussions, and partakes rather of the nature of a series of essays on the set subject. Christmas having intervened, the discussion on Dr. Copeman's paper, read on December 10, was adjourned until January 14, when he repeated that part of his demonstration which dealt with the transference of smallpox through monkeys and calves, and the vaccination of children with lymph so obtained. These experiments, you will remember, satisfied him that vaccinia is really an attenuated form of variola.

Professor Sims Woodhead then resumed the discussion. He fully confirmed Dr. Copeman's observation on the effects of the addition of glycerin to lymph. He considered if a lymph showed many sport-bearing organisms, it had not been properly collected. He did not believe that the glycerin diminished the potency of the virus for three or four weeks, but after that time there was a decrease of the activity. Nor did he believe that more local inflammation was caused by glycerinated lymph— most of the local effect was produced by extraneous organisms [illegible] with imperfect preparation.

Dr. T. H. Acland followed, and discussed at considerable length the origin of lymph, its preparation and use. He advocated the supply of standardized lymph by the Government to all practitioners, thinking it possible that Calmette and Guérin's method [illegible] the difficulties of standardizing. Glycerine had long been used to dilute lymph, but it was reserved for Dr. Copeman's researches to show that this was not a mere harmless diluent, but was capable of producing a sterile lymph. He urged that there ought to be established a minimum standard of efficient vaccination, and referred to the figures of the Royal Commission of 1896 which show, in [illegible] cases, a mortality from variola of 6.2 among patients with one mark as against 1.2 among those with four. He referred to treatment with serum from a vaccinated calf, but admitted that the work done in this direction was not conclusive.

Professor Haccius of Geneva said that during a scarcity of good lymph in 1892, he succeeded in transmitting variola to the calf, and after passing the virus through seven calves inoculated a child, with the result that typical vesicles formed. Stumpf had confirmed this. Chauveau had objected, and inoculated a cow and then a child with the result that the child had variola. Professor Haccius held that this was a direct transference of variola to the child, the cow being merely a stage in the transference. He thought that vaccinia and variola would be proved to be identical, but it was generally known that some cases of variola could not be transmitted to the calf.

The discussion was then adjourned again until January 28, when it was resumed by Dr. Sidney Coupland, who held that the Act of 1898 had proved beneficial by making glycerinated lymph obligatory, and so diminishing bad effects, the infective organisms being removed. He thought the Government should have control over all lymph employed. With the purified lymph there might be so little scarring that the number of scars rather than their area or depth must be looked to as the sign of efficiency. It was certain that those who had more scars were more protected. About one in four persons vaccinated in infancy would contract smallpox on exposure to the infection when grown up. In children under ten years old, the liability was only one in twelve, but in the unvaccinated it was two in every three. Recently vaccinated persons were more completely protected than those who had been done for a long time. Revaccination conferred practical immunity. Exceptions would be due to the lymph having become partially inert. But even smallpox itself did not confer absolute permanent immunity, second attacks of the disease being known to occur.

Dr. A. E. Cope gave details of the method he carried out as a public vaccinator. Cleansing the arm with spirit of carbolic lotion, boiled water, a pledget of wood-wool after the operation, delay until some erythema appeared, and then covering the scratches with a boric pad, to be renewed in a week. He preferred a platinum lancet with a hard iridium point, as it can be heated in flame, and did not look dull or dirty after it. Revaccination would succeed at about fourteen years of age, and was then less likely to give rise to a sore arm than if delayed until later life.

Some questions were put by other speakers, and then Dr. Copeman replied on the whole discussion on his paper. He maintained that the glycerin inhibited and gradually eliminated all the non-sporing organisms, and they are the pathogenic ones. The same degree of vaccination was needed by the child as the adult, and vesiculation is less severe in the child, for the same amount of lymph introduced. No method of standardization had been discovered, the only test was the clinical effect. No doubt some persons had had smallpox twice and a few even three times. The glycerinated lymph destroyed less cutaneous tissue than was formerly common. Every one should be revaccinated. In proof of the immunity obtained, he said he had twice been accidentally inoculated from confluent smallpox without any ill effect. He did not think the new lymph less potent than the old. The epithelium in which the vaccine organisms were supposed to reside was included in the calf pulp employed in preparing the lymph, while in the old plan only the clear liquid from the vesicles was used.

At the Medical Society we have had a discussion on obesity. It was begun by Sir T. Lauder Brunton, who remarked that the accumulation of fat took place chiefly in the subcutaneous tissue, in the omentum, and around the heart and kidneys. Obesity began when the amount of fat became inconvenient. The cause was the ingestion of more fat-making food than could be burnt off, the treatment, therefore, is limitation of both the quantity and quality of the food, and increase of combustion of the body by increasing the circulation. To accomplish the latter muscular exercise is the best plan, and if from any cause the patient cannot take this, massage should be tried, as it can increase the circulation through the muscles, [illegible] and thus promote tissue change. But massage alone is not enough, and should only be considered as a preliminary to active exercise. Food must also be lessened. This could be done more easily by [illegible] and fluids being taken separately. Too often food is washed down by fluids which might otherwise be left. Dry toast and biscuits were less easily swallowed, and so a less amount ingested. If diet and exercise fail the Salisbury plan could be tried, but it produced excessive nitrogenous waste products, giving rise to poisonous effects unless perfectly eliminated. Thyroid extract produces tissue waste, but soon sets up nervousness, tremor, and tachycardia.

Dr. Burney Yeo said obesity from dietetic error was easy to remedy, but hereditary cases, or those due to a vice of metabolism, were not much benefited by withdrawing carbohydrates. Treatment should be begun early. A man of forty who showed a tendency to lay on fat should leave off sugar and eat less bread and potatoes. Alcohol, too, produced obesity. Water must not be too much restricted, as it is necessary to carry off the waste products. He doubted if internal secretion was as important as generally supposed, and suggested that the effect of castration was rather due to the loss of sexual emotions. Thyroid should only be given after other treatment failed. The Salisbury treatment was risky in elderly people.

Dr. Schott of Nauheim confined his remarks to fatty heart. It was formerly common to use purgative waters so as to cause rapid reduction of weight. This was dangerous in anæmic or elderly patients. If fat was lost rapidly, it was not only in the subcutaneous tissue, but in the brain, nerves, and muscles. Reduction should, therefore, be gradual. Cool effervescing baths were better for the obese than Turkish. The exclusive diet of milk or dry rolls were only hunger cures.

Dr. R. Hutchinson favored thyroid treatment, as it oxidized the fat in the body, though it also oxidized albuminoids, and so greatly increased excretory products. He said limitation of fluid did not experimentally diminish weight, so the result must be due to less food being partaken of.

Mr. Keetley thought, in some cases, fat on the abdomen might be removed by operation.

Dr. Luff said Salisbury treatment must not be employed when there was renal disease or cardiac weakness; nor should thyroid in such cases. No fluid with meals was a good rule.

The President, Dr. Allchin, said, though excess of food was a common cause, some persons would get fat on very little, while others who fed largely kept thin. The nervous system had some influence. Mentally deficient children were often very fat, as also do cases of "adiposa dolorosa." On the contrary, patients with anorexia nervosa wasted out of proportion to the decreased food taken. He thought that in obesity there was some perversion of metabolism.

Surgeon-General Taylor, the new Director General of the Army Medical Department, is now in full work, and on the 31st ult. distributed the prizes at Netley, and addressed the officers who had received commissions.

Dr. Lankester of Leicester died on the 30th ult., aged seventy-six years. Dr. Coppin, on the 31st, at Plumstead, in his ninetieth year. Dr. Stowers of Clapham, on February 3, aged eighty-seven years. Closely connected with the profession was Mr. Martindale, author of the "Extra-Pharmacopœia," a past president of the Pharmaceutical Society, and teacher of pharmacy at University College. He died suddenly on February 2, aged sixty-one years. He was greatly respected by a very large number of professional acquaintances.

THE PRECIPITATION OF PROTEIDS CAUSING THROMBOSES IN DIABETES.

To the Editor of the Medical Record:

Sir: Will you do me the kindness to correct in an early issue of the Medical Record a reported error in the discussion on "Diabetes" at the January meeting of the Medical Association of the County of New York, which appeared in the issue of the Medical Record of February 15, 1902. I was evidently guilty of a *lapsus linguæ* when I stated that Dr. E. Libman of New York had discovered that "when the percentage of glucose was the same as in diabetic blood, that is from 0.2 to 0.4 per cent., the bacteria grown on such media precipitated the *peptones*. This might indicate that bacteria abounding in the blood might precipitate the peptones and account for the occurrence of thrombosis and furunculosis." I should have said proteid instead of peptone. Dr. A. Lambert was quite right in making the criticism, which I tried to correct then, but which your reporter did not apparently hear. As the report now stands a manifest injustice is done, for which my slip of the tongue is to blame, to the important discovery of Dr. E. Libman that some bacteria have the property in certain percentages of glucose of throwing down a proteid precipitate from serum. If this could be demonstrated to occur in the living body it might be of great significance in explaining certain thromboses and some forms of local infections in diabetics. N. E. Brill, M.D.

OUR PARIS LETTER.

(From Our Special Correspondent.)

The Operation on the Hindoo Twins.

Paris, February 14, 1902.

The operation on the Hindoo twins, which has just been performed in Paris by Dr. Doyen, has caused a great deal of comment, on account of the circumstances attending it, and the discussion between physicians which has resulted therefrom. One of the internes of the Hopital Trousseau, to which the Hindoo twins were taken at first, gave me the requisite information as to what took place in that institution. The woman who has had charge of the twins at the Barnum and Bailey show was obliged to consult a physician at the Trousseau Hospital (Dr. Guinon), on account of the health of Doodica, who has shown signs of failing health. According to the lay papers, who are able to publish an account of the disease, both sisters are suffering from a beginning of tuberculosis of the lungs, and Doodica, moreover, has shown signs of tuberculous peritonitis.

Professor Kirmisson, who is professor of clinical surgery for children, was consulted, and he recommended an operation, which, however, he refused to undertake unless he had a written statement from the Barnum and Bailey agent, or from the foster-mother, giving him the requisite permission. This was not immediately forthcoming, and at last the woman previously mentioned said she would give the permission provided she could attend the operation and have a cinematographic copy of the operation.

This Dr. Kirmisson very properly refused, and the twins were thereupon taken to Dr. Doyen's clinique, where the operation was done on Sunday afternoon. This lasted exactly twenty minutes, according to the *Echo de Paris*, a journal which gives what is presumed to be Dr. Doyen's description.

The sisters were placed on a sterilized cloth and subjected to narcosis. Dr. Doyen placed himself on the right, and cut the skin above the connecting ligament. Then a certain amount of cartilage was incised with a lancet, and two small veins tied. The peritoneum was then cut, and the hepatic band, which is found in such cases, was exposed. A few adhesions were found on Doodica's side, who was suffering from tuberculous peritonitis. The hepatic bridge was 7 cm. long and 4 cm. in diameter, and seemed very vascular. Dr. Doyen used here his double-lever forceps, which gives a pressure of 2,000 kilograms. Two ligatures *en chaîne* were sufficient for Radica and were made with catgut. The pedicle, which was very short, was then seized and cut, and on Doodica's side three arteries were immediately seized with pincers and ligated. Two ligatures *en chaîne* were then carried out, and the skin on the back part was cut through. The abdominal opening was then sewn up, only a small aperture for a lint drainage being allowed.

The whole performance was photographed with a cinematograph. The operation only lasted ten minutes. According to Dr. Fort, this operation has only been carried out once, in Brazil by Dr. Chapost-Provost. The night after the operation, Doodica's temperature fell to 36° R., while Radica's went up to 38.5°, with a pulse rate of 120. On Tuesday, however, the temperature of Radica had become 37.6° R., and her pulse 110; Doodica's temperature was 37.2° R., and her pulse 96. One of the twins died a few days after the operation. The other is now doing well and will probably recover.

Since the operation, Dr. Doyen and the Trousseau Hospital authorities have had a controversy. Dr. Doyen had made the statement that the girls had been worried by curious students, so Dr. Guinon emphatically denied this statement. Dr. Doyen thereupon made matters worse by writing to the press that they had reached his establishment covered with vermin, very filthy and their mouths filled with thrush. He was obliged to leave them alone for two days, so frightened were they at the prospect of another examination.

CATS AS CARRIERS OF DISEASE.

To the Editor of the Medical Record:

Sir: Your comments (p. 220) on the connection of cats with the diphtheria epidemic at Knowlton, Canada, induce me to state that, in 1883 (prior to the discovery of the Klebs-Löffler bacillus), I had an experience which has caused me ever since to banish cats from rooms occupied by diphtheria patients.

Two farmer's children, suffering with diphtheria, had a favorite cat, which was with them much of the time for the first week of their illness. On the fifth or sixth day of their sickness I was asked to see the six-year-old daughter of their next neighbor, who lived about one-fourth mile from them. I found her with a well-marked case of diphtheria. They stated positively that there had been no communication between the two houses, as the little girl had had an attack of diphtheria when she was about two years old, and, being their only child, they had avoided every case of sore throat since then.

On my visit next day *I found the girl fondling the boys' cat*, and learned that, when well, the children were constant playmates, and that the cat was as much at home at one house as the other.

The next day the cat seemed sick, and died that night. I made a post-mortem examination, and, judging from the condition of mouth and throat (which were lined with false membranes), decided that the cat had died of diphtheria, and had been the means of spreading the disease from the boys to the girl.

Three other cats on the first farm died with all the throat symptoms of diphtheria.

One of the boys died; the other recovered, as did also the girl.

Those who have the means of making bacteriological tests should give this subject careful study.

H. S. Jewett, M.D.

Dayton, Ohio

HYPODERMOCLYSIS IN TUBERCULOSIS.

To the Editor of the Medical Record:

Sir: In our frantic efforts to discover a specific for pulmonary tuberculosis we have almost wholly overlooked the administration of decinormal salt solution by hypodermoclysis. This remedy, if not a specific, is at least a most valuable addition to our resources in dealing with cases of mixed infection. It is cheap, always at hand, and easily administered.

I am using it in five cases characterized by fever, night sweats, severe cough, profuse expectoration, hæmorrhage, loss of weight and general prostration. The results so far have exceeded my expectations. In every case the temperature was reduced to normal, and, by repeating the injections once a week, a nearly nominal temperature has been maintained, night sweats have been greatly relieved, the action of the heart strengthened, the appetite improved, a general abatement of the more troublesome symptoms, and a feeling of well-being induced. It is too soon to speak of its curative effects, but it does add greatly to the comfort of the patient, keeping him in a condition in which he is more likely to respond to other remedial measures. From two to four ounces, slowly injected, at a temperature of 102° F., causes very little pain, and under the influence of light massage and wet cloths, applied as hot as can be borne, absorption takes place quickly, leaving only a slight soreness, which usually disappears in the course of twenty-four hours. The site selected for the injection is the ilio-lumbar region, as advised by Kemp.*

I make no claim to originality, but write with the hope that other physicians may be encouraged to give this method a trial and report the results obtained.

Joshua L. Barton, M.D.

57 E. Fifty-fifth Street, New York.

Huxley on Darwin.—To any one who studies the signs of the times, the emergence of the philosophy of evolution, in the attitude of claimants to the throne of the world of thought, from the limbo of hated and, as many hoped, forgotten things, is the most portentous event of the Nineteenth century. But the most effective weapons of the modern champions of evolution were forged by Darwin; and the "Origin of Species" has enlisted a formidable band of combatants, trained in the severe school of physical science, whose ears might have long remained deaf to the speculations of *à priori* philosophers.

Progress of Medical Science.

Boston Medical and Surgical Journal, February [illegible]

On the Value of Modern Methods of Diagnosis and Treatment in Gastro-Intestinal Diseases.—[illegible] [illegible] the diagnosis and treatment of gastric disorders [illegible] that they have [illegible] diagnosis in cases of gastric disease [illegible] the details and [illegible] of the methods [illegible] to the many [illegible] of the patient, but [illegible] illustrating their value. In the first case there was a low acidity, a large amount of mucus, and a large but not dilated stomach. In the second case the most notable features were [illegible] hours after the test meal, and with an acidity nearly as high as is usually found one hour after a test meal, [illegible] after the test meal, and a [illegible] dilated stomach. The author asks how except by these modern methods could these conditions have been ascertained and whether the knowledge of them is not absolutely necessary to rational treatment.

The Treatment of Eclampsia by Stroganoff's Method.—S. Newell describes this treatment in brief as follows: The administration of oxygen during the convulsions; the use of morphine and chloral to control the convulsions; the free use of cardiac stimulants when the heart action weakens; prompt delivery when the convulsions do not yield to treatment, a milk diet, and the avoidance of all methods of treatment which tend to depress the patient. The conclusions deduced by the author from his experiments are: (1) In post-partum eclampsia the use of morphine and chloral in combination seems to have a distinctly beneficial action in controlling the convulsions; (2) In ante-partum eclampsia the treatment is less efficient, but the course of the disease seems to be altered for the better in the majority of cases; (3) Although the treatment has not given as good results in the author's cases as in those of Stroganoff, a further trial is indicated, since the results have not been any worse than under any other method, and there may have been errors in the application of the method which can be remedied.

Journal of the American Medical Association, February 22, 1902.

Report of a Typhoid Epidemic at the Iowa State Agricultural College.—W. E. Harriman gives the report of the epidemic. The total number of cases was sixty-five, of these twenty-three went to their homes, leaving forty-two to be cared for, thirty-three males and nine females. Of this number only two died. No unusual features were presented either in the clinical course of the cases or in the treatment which was carried along the modern lines. The outbreak was pretty definitely traceable to infected milk.

The Identification of Criminals Through the Fundus of the Eye.—M. F. Weymann contends that anyone can at any time, with certainty, be identified by the anatomical conformation of the fundus oculi, in fact, the disposition of the arteria centralis retinæ and its branches alone would be sufficient for the purpose. Absolute identification can be obtained by a drawing (exact as a photographic reproduction) or nearly so, of the papilla and a surrounding retinal circle distant from the scleral ring by two papillary diameters. So great is the multiplicity of the anatomical relations of the vascular twigs that he has never been able to find even two fellow organs exactly alike. The points to be considered are:—(1) The method of division (dichotomous or otherwise); (2) The exact point of division; (3) The exact angle of the vessels with the primary meridians; (4) The exact distance of one divisional point from the other; (5) The relative size of the divided twigs; (6) The angle of division; (7) The course of the twigs (straight, curved, etc.); (8) The exact distance everywhere and at every point, between venous and arterial branches (parallelism, convergence or divergence, twining, etc.).

Median Perineal Prostatectomy; Total Removal of the Prostate Gland.—Six cases are reported by A. H. Ferguson. He thus enumerates the advantages of the operation:—(1) It is the most direct route to the prostate; (2) Injury to the bladder is avoided; (3) The operation can be quite easily performed. Even where the gland has been repeatedly inflamed it is not so hard to remove it from below as from above; (4) It is an advantage to remove the gland piece by piece, for the surgeon can work through a small opening without bruising the surrounding parts; (5) Hemorrhage is avoided so long as one is careful to work within the capsule. The hemorrhage in suprapubic prostatectomy or in the combined method is often very alarming. Sepsis and intoxication from pus and fetid urine coming in contact with the prevesical tissues and wounded and raw surfaces within the bladder are sources of great danger in the suprapubic operation; (6) Perineal drainage is more complete; (7) The danger from septicæmia is not at all prominent after perineal prostatectomy, whereas [illegible] absorption of septic material is the [illegible] in the suprapubic operation; (8) There is less danger of uræmia. The operation consuming less time and the short anæsthesia affects the kidneys less, and there being a continuous opportunity for [illegible], there is less work for the kidneys to perform; (9) The perineal operation is accompanied by far less shock than the author has noticed following suprapubic prostatectomy.

New York Medical Journal, February 22, 1902.

General Anæsthesia and its Administration in Throat Surgery.—M. L. Maluro comments on the fact that in throat surgery we often have the administration of the anæsthetic interfered with by enlarged tonsils, adenoids, etc., and calls attention to the following practical points in the use of nitrous oxide gas:—(1) It should be carefully ascertained that the valves of the gas apparatus fit accurately, thereby establishing the certainty of a rapid exit of atmospheric air from the lungs; (2) A certain amount of rebreathing of nitrous oxide should be allowed at the end of each inhalation in order that a longer gas, and a shorter ether anæsthesia may be obtained; (3) The transition to ether should be accompanied by a rather free amount of admixture of air through the various inlets in the apparatus without removing its facepiece; (4) Lastly, the head of the patient should be well drawn back, and forward pressure made on the jaws at the time of the transition to ether, so that the air-way may be increased to its utmost.

A Critical Review of Some of the Recent Literature of Tuberculosis.—J. Wright discusses some of the theories concerning tuberculosis that have been entertained in time past, and states what he believes to be the convictions of the majority of physicians at the present time. He rather decries the drastic measures of some of our health boards, and believes that there are other factors in tuberculosis than the mere presence of the bacillus. He does not believe it possible to produce any material effects on the mortality of the disease by isolation or any other measure it is possible for the State to enforce. The thing to do is to strengthen the individual index of resistance, and that is to be done by better lodging for the poor, shorter hours of work, more public parks, prohibition of child labor, etc. He believes that the changes in these respects for the last fifty years are responsible, or rather account for the lessened death rate of the malady. As regards the present discussion relative to the human bacillus and that infecting cattle, he does not think that we can draw any positive conclusions, for the results of various experimenters are conflicting. All we can do is to continue our observations, and in the meanwhile desist from the dogmatic statements.

The "Poultice Method" of Healing Cutaneous and Subcutaneous Abscess Cavities.—M. B. Hutchins' method is simply to apply over the opening of the abscess a poultice of flax-seed meal, made with three-per-cent. carbolic instead of plain water. A thin cloth or gauze layer can be put next to the opening. The three per cent. of carbolic acid really becomes about one per cent. in the mixture, and is hence very weakly germicidal. Absolutely nothing is put in the abscess cavity, it simply being emptied of pus by pressure—through a small opening—if not already open. The poultices are changed as often as cleanliness or their getting dry requires. The wet poultice affords constant drainage and absorbs the discharge. The moisture in the poultice and the constant flow of discharge prevent premature union of the mouth of the cavity. There is no painful packing in of gauze strips and retardation of healing by the presence of the foreign substance—gauze. There is no reinfection in dressing and there is a saving of from 75 to 80 per cent. in time of healing. When incision is necessary it may be small, instead of "free" and long. The pressure of the poultice aids in the coaptation of the walls, and the rapid removal of discharge clears the way for natural reparative processes. The successful use of rubber adhesive plaster on some occasions shows the effect of simple warmth and moisture in facilitating healing from the bottom.

American Medicine, February 22, 1902.

The Indications for Perineal Section in Stricture.—G. Frank Lydston declares that the most imperative indication for perineal section is traumatic stricture. Early operation, particularly in traumatic stricture, is likely to be followed by permanently good results. As a general proposition, the writer believes that it is wise in every case of indubitable traumatic stricture, in which complete relief from symptoms cannot be obtained by the sound, to perform a thorough operation by perineal section, and if the adventitious tissue be at all extensive, to excise it. It is not necessary that the stricture be extensive in order to demand perineal section. Strictures complicated by fistulas or severe cystitis demand perineal section. By this operation alone it is possible to thoroughly remove the obstruction and drain the infected deep urethra, prostate, and bladder. Surgically, impermeable stricture is by no means so infrequent as many believe. Under these conditions, perineal section without a guide may be necessary. As to the success of perineal section—with a thorough operation, involving division of all fibroid tissue, both on the floor and the roof of the canal, and when necessary, the excision of encircling rings and nodules of fibroid tissue, the operation is a perfect success, as regards permanent cure, in a large proportion of cases, granted that the after treatment is conducted intelligently. Sounds should not be used too assiduously in the after treatment.

The Etiology of Yellow Fever.—Walter Reed and James Carroll give an account of some recent experiments in yellow fever. For purposes of inoculation, they used three kinds of material: (*a*) Unheated and partially defibrinated blood; (*b*) Partially defibrinated blood which had been heated to a temperature of 55° C. for ten minutes, and (*c*) Diluted blood-serum which had been filtered through a Berkefeld filter. Since three nonimmunes received without any disturbance to health double the quantity of *heated* and partially defibrinated blood that sufficed when *unheated* to cause an attack of yellow fever, it follows that the specific agent present in the blood in yellow fever is destroyed or at least greatly attenuated by a temperature of 55° C. maintained for ten minutes. Of the three nonimmunes who received a subcutaneous injection of filtered blood-serum, two developed an attack of yellow fever. The serum had been slowly filtered, and as soon after as possible the filter was resterilized by steam and tested as to its effectiveness in preventing the passage of bacteria. For this a recent bouillon culture of *staphylococcus pyogenes aureus* was used, of which 50 c.c. were passed through the filter. The filtrate thus obtained was transferred in quantities of 10 c.c. to each of two flasks containing 200 c.c. of sterile bouillon, which were incubated at 37° C. for four days, and thereafter kept at room temperature for ten days longer, at the end of which time no growth had occurred. So this filter was reliable. The production of yellow fever by the injection of blood-serum that had previously been passed through a filter capable of removing all test bacteria is a matter of extreme importance. The occurrence of the disease under such circumstances, and within the usual period of incubation, might be explained in one of two ways: first, upon the supposition that the serum filtrate contains a toxin of considerable potency; or, second, that the specific agent of yellow fever is of such minute size as to pass readily through the pores of a Berkefeld filter.

Against the view that a toxin is present in the serum filtrate, the writers invite attention to the innocuousness of the partially defibrinated blood when heated to 55° C., for ten minutes. This has been shown by negative results in three cases which they report. Here the toxin, which must have been present in just the same quantity as in the serum filtrate obtained from this blood, appears to have been completely destroyed by the temperature above mentioned. Now, although certain bacteria are destroyed by this temperature, as yet there is no bacterial toxin known that is rendered inert by such a low degree of heat continued for so short a time. According to Kitasato, the tetanus toxin, which so far has proved to be the most sensitive, requires a temperature of 60° C. for twenty minutes, or 55° C. for one and one-half hours in order to destroy its activity. In one case which is reported in this paper, the results were negative after an injection of serum filtrate, but a mild attack of yellow fever followed a subcutaneous injection of blood drawn from the venous circulation of a yellow-fever patient early in the fourth day of the disease. The writers, therefore, feel justified in expressing the opinion that the infection in this case must be attributed to the injection of the blood, rather than to that of the filtered serum. And further, that the blood of this patient contained the specific agent of yellow fever, which had, therefore, passed through the filter along with the filtrate with which this latter individual had been inoculated.

Medical News, February 22, 1902.

Some Notes on the Prophylactic Screen in the Treatment of Tuberculous Conditions of the Larynx and Pharynx.—Stephen W. Wells describes this screen: It consists of a sliding iron upright set in a weighted base; at the upper end of the upright is attached a metal frame holding a glass plate which can easily be removed and cleaned. The frame is attached to the upright, so that when in use the right arm is but one-third the length of the left arm. This arrangement allows considerable freedom in handling the instruments on the right, while the left hand is passed under the screen, thus easily controlling the laryngoscope. Experiments have been made with the scrapings of the side of the glass facing the patient, and tubercle bacilli were found to be frequently present. This screen has the advantage of being adjustable to any height; it can be easily placed in position, it does not interfere with the view of the larynx; it relieves the patient to feel that he cannot cough into the physician's face; and it thoroughly protects the physician. It has been found to possess no disadvantages in the author's experience.

The Pathology and Etiology of Prostatic Hypertrophy: Suprapubic Drainage and Myomectomy Considered as Methods of Treatment and Cure.—Augustus Charles Bernays states that prostatic hypertrophy, when microscopically examined, is found to consist of an increase of the non-striated muscle cells and connective tissue which lie between the tubular glands. These latter are displaced by the hypertrophic muscle fibers, and in extreme cases are nearly absent. The etiology of this affection has not yet been cleared up. In old cases, palliative measures are sometimes preferable to radical ones. Drainage of the bladder by the suprapubic route is preferable to perineal drainage in cases of cystitis, because this method gives the sphincter apparatus more complete rest than the perineal buttonhole or fistula. In recent cases, when the patient's health has not been injured by the complications common to this affection, the dangers of myomectomy or perineal prostatectomy are minimal, and in these cases a radical and functionally satisfactory result can be achieved by myomectomy. Operation must be regarded as a palliative measure intended to enable the patient to evacuate his bladder more completely than before. It will probably fall into disuse as the technic of myomectomy or perineal prostatectomy is perfected. Bottini's operation is dangerous. Myomectomy done through a median perineal incision is the operation which promises the best results and is the operation of choice. It is applicable to the greatest number of cases in which permanent cure may be expected, the kidneys being physiologically sufficient and unimpaired. The perineal fistula will always close spontaneously after the perineal drainage is discontinued, and if enough mucosa has been left there will be no stricture.

Philadelphia Medical Journal, February 22, 1902.

The Treatment of Lateral Curvature.—James K. Young believes that any form of lateral curvature which may be benefited at all by treatment, is best treated by light gymnastic exercises. The introductory part consists of light exercises taken in the horizontal position lying on a table. Special attention is given to breathing exercises. Weak muscles are developed by exercises adapted to them individually or collectively. The weak muscles are slightly over-developed by first finding the best voluntary position which can be assumed by the patient and then taking all the exercises in that position. Special attention should be paid to the development of the lower extremities. The greatest care should be observed and the patient ought always to be under the observation of the surgeon. The treatment should be given daily for periods of from three to six months. Those exercises which are found to be the most useful should be used, supplementing them from time to time with others. The writer approves of daily massage after the exercises. This should consist of several different movements intended to improve the weaker muscles, to divert the blood from the spinal column, and to rest the patient after exercises. The exercises should be taken daily except Sundays and during the menstrual period. The exercises may be modified during the summer. Sometimes they may be discontinued at this season. These patients should not go to school, nor should they go out in society, as these duties interfere with the proper amount of rest. The morning of each day should be devoted to treatment, and at least two hours in the afternoon should be spent in the prone position. Late hours should be forbidden. All games which employ one side of the body more than the other are also to be forbidden.

On the Relationship Between Human and Bovine Tuberculosis.—J. G. Adami concludes that bovine tuberculosis is easily conveyed from cattle to cattle, and whatever the method, for they are various, this transmission from one animal of the bovine species to another is by far the commonest mode of infection in cattle. Human tuberculosis is transmissible to cattle. Mixtures of tubercle bacilli with other microorganisms (as in sputum) appear more infectious than pure cultures. Swine appear to be fairly easily infected with both human and bovine tubercle bacilli. Human tuberculosis in the majority of cases is conveyed from human being to human being by the inhalation, more rarely by other methods. Everything points to the fact that in the main the cases causing infection in man are derived from previous cases of the disease in man. By sojourn in the human body and passage from man to man the human tubercle bacilli have acquired properties differing from those possessed by bacilli which have passed through cattle. These differences are not so marked as to permit us to conclude that we are dealing with different species. Bovine tuberculosis can be transmitted to man either through wounds or through the digestive tracts. By passage through cattle the tubercle bacillus gains increased virulence for cattle, but lessened virulence for man. Save in cases of wound infection there is a lack of evidence that bovine tubercle bacilli infect adult human beings. It is infants and children who are liable to be infected, and then through the agency of milk. The indications are that infection is brought about only by the use of milk of cattle which are very extensively diseased, more especially of those suffering from udder disease. Animals showing physical signs of tuberculosis and especially those with udder tuberculosis, should be condemned and under no circumstances should their milk be used as food. When the disease is in a herd, Bang's method should be employed and the animals reacting to tuberculin separated from the healthy ones. Pasteurization of milk will lessen the danger of the transmission of tuberculosis from cattle to man.

The Lancet, February 15, 1902.

The Medicinal Use of the Pressor Substance of the Pituitary Body.—F. Golla calls attention to the recent work of Schäfer and Vincent, who were able to demonstrate the existence of two substances in the infundibular part of the pituitary gland having distinct physiological properties, one of these producing a rise and the other a fall of blood-pressure. These two bodies they distinguished as the pressor and depressor substances. Of these they found that the pressor substance is soluble in salt solution and insoluble in alcohol and ether, whilst the depressor substance is soluble in all three. The active substances are not destroyed by boiling. For clinical purposes, the pressor substance, purified by repeated washing of the alcoholic precipitate with ether obtained from 80 gr. of the dried infundibulum, was dissolved in 30 ♏ of normal salt solution. The injection of 3 ♏ of this solution into the mucosa of the lower jaw caused a local vasoconstriction; the mucosa remained blanched for about forty-five minutes, for a considerable area around the point of injection. On injecting 5 ♏ subcutaneously into the right forearm, there was a perceptible pallor of the finger nails for a few minutes. The pulse rate fell from 95 to 84, and the wave was appreciably fuller. A subcutaneous injection of 8 ♏ of the saline extract was given to a patient with advanced Addison's disease. The radial blood pressure was 120 mm.; the pulse rate 100. Two seconds after the injection, the patient complained of a sudden spasmodic contraction of the muscles of the arm and fingers. Immediately after injection the radial pulse almost disappeared, but this was found to be due to local muscular spasm. Previously to injection the patient had complained of feeling uncomfortably hot, and a couple of minutes afterwards he spontaneously remarked that "all the heat seemed to have gone inside." Two hours after the injection the pulse was 80 and much stronger and fuller. The patient still complained of feeling cold at the extremities. Three hours after the injection the blood pressure was 135 mm. There was marked diuresis during the twenty-four hours succeeding the injection; the urine was acid with a specific gravity of 1010. There was no glycosuria, an effect frequently noticed after suprarenal injection. Golla has taken considerable quantities of the pressor substance by the mouth, but has never seen any result, although the substance is unaltered by peptic digestion and is dialysable. The pressor substance would appear to be proteid in nature. The iodine found in the pituitary body is not apparently in combination with the pressor substance. Its cardiac, vascular and diuretic action would indicate that it may prove to be of service in cases of heart disease.

The General Pathology of Tumors.—In the first and second Erasmus Wilson lectures, C. P. White classifies new growths and discusses the rudiments from which they arise. He then considers cell structure and cell division, and finally passes to the parasitic theory of causation. He enumerates the arguments in its favor as follows: (1) The apparent resemblance of carcinoma to infective diseases such as tuberculosis. (2) The inoculability of malignant growths. (3) The analogy with the lesions produced in the rabbit's liver and elsewhere by the coccidium oviforme. (4) The topographical distribution of cancer. Concerning the objections to the theory, he says that we know of no disease characterized by definite anatomical lesions which is at the same time characterized by a definite extrinsic causal factor. Therefore, since tumors are characterized by their anatomical structure, we should not expect them to be due to definite extrinsic causal agents. In the first place, we know of no parasites which are capable of producing primarily a proliferation of cells. The proliferation of epithelial cells in carcinoma, he thinks, is not primary, and even if a parasite were capable of causing a primary proliferation it would not explain the occurrence of a carcinoma, since the essential lesion of carcinoma is not proliferation, but is penetration of the epithelial cells into the connective tissue. In the next place, the reaction of the organism against all known parasites, animal and vegetable, is of a defensive nature, and characterized by the phenomena of inflammation. The parasite first gives rise to injury or destruction of the tissues; this is followed by exudation of leucocytes, which remove the damaged tissue and, if possible, the parasite, and this, again, by proliferation of the surrounding tissue, which repairs the injury. In carcinoma proliferation takes place in a centrifugal direction, instead of a defensive reaction, there is produced an ever increasing amount of epithelial tissue in which the parasite can grow and multiply. This is so opposed to the accepted laws of parasitism that one may be excused for doubting its possibility. Some have supposed that the parasite acts on the cell in somewhat the same way as a sperm cell acts on a germ cell and thus induces proliferation. This supposition is negatived by the fact that the parasite-containing cell does not undergo division. As regards metastatic growths, the author says they cannot be due simply to the presence of a parasite, for if they were we could not have a metastatic carcinoma in a position devoid of epithelium. We must therefore conclude that, besides the parasite, at least one epithelial cell must be transferred from the primary growth to form the mother cell of the secondary deposit, but this cell cannot be the cell in which the parasite is lodged, since the parasite-containing cells, at least in the case of the described parasites, do not proliferate, but undergo degeneration. Therefore we must imagine a parasite and a cell independently conveyed to the site of the metastatic growth. Again, this theory will not explain the frequency of malignant disease in the female organs of generation or the rarity of it in the lungs and small intestine. Nor does it explain why the acini of the breast are more frequently affected than the ducts. In the case of sarcoma it is even more unsatisfactory, since, except in the rare cases of sarcoma starting in a wound, we must suppose the parasite conveyed to the seat of the tumor by the blood, and if this were the case we should expect multiple primary growths to be common. It is equally impossible, White holds, to explain the occurrence of tissue tumors on the parasitic theory, although if they are due to extrinsic causal factors, these factors must necessarily be of a parasitic nature. It might be said that extrinsic factors are not necessary to explain simple tumors, but we cannot so separate cell and tissue tumors as to say that the former are due to intrinsic factors and the latter to extrinsic factors.

British Medical Journal, February 15, 1902.

The Disinfection of New Clothes.—Charles A. Cameron states various instances in which he is assured that the infection of scarlet fever was carried by new clothes. He noticed the outbreak of this disease repeatedly among the recruits of the Royal Irish Constabulary. After investigation, he discovered that the clothes of the recruits are made largely by women for the contractor. Suspecting that they were the carriers of the infection, he ordered that these clothes should be sterilized before they were received into the barracks. The sterilization began at the end of April, 1901, and from May 15, to the present writing, January, 1902, no further cases have occurred.

Treatment of Chronic Eczema.—Alfred Eddowes thinks that as our knowledge of bacteriology and pathological processes increases, the term eczema will be less often used or will be more often qualified. The object of all treatment is to bring back the diseased condition to a healthy and physiological state and keep it there. Special indications must be met, in each case. If injury is being done by scratching or friction of any sort, the part must be soothed and protected or treatment may be almost useless. Gentle pinching or pressing will often afford the relief of scratching without its injury. Eczema may have many associated causes and complications. General treatment is essential in many cases. Gray powder, calomel, decoction of aloes, citrates and carbonates, iron, quinine, and strychnine, and sometimes colchicum will meet almost all needs for internal medication. The regulation of diet is sometimes most necessary. In the case of children, meat juice or blood gravy, for sucklings, and codliver oil or malt extract for older ones, will often do wonders, as will also now and then change of air and the administration of thyroid extract. For adults, sometimes a change of occupation is sometimes necessary, but this is rare.

On Diphtheria Antitoxin Eruptions.—Arthur Stanley reports observations made on a series of 500 cases of diphtheria. They were all treated with antitoxin. Skin eruptions appeared in about one-fourth of the cases. The period of onset was usually during the second week after the giving of the antitoxin. The eruption constitutes a distinct type. The typical eruption is a marginate erythema on the psoriasis regions, tending to run into arcs of a circle, lasting about three days and accompanied by slight *malaise*, and a rise in temperature of about 3°F. The margins are raised and turgid. The lesions begin in macules, become rings, increasing in diameter, until the adjacent rings coalesce and break the arc. The spread of the rash is most frequent from face and trunk to limbs, and from extensor to flexor surfaces. It lasts from two to five days, but may exist for only a few hours, when of a scarlatiniform nature. The occurrence of an antitoxin eruption during the course of a case of diphtheria did not appear to influence the prognosis seriously, though it must be admitted that any febrile disturbance of the heart would tend to have a harmful effect. No case in this series, however, was observed in which heart failure was precipitated by the occurrence of an antitoxin eruption.

Airborne Typhoid.—R. H. Quill reports an epidemic of typhoid which occurred in a large camp in the hills of the Island of Ceylon where the Boer prisoners of war were being kept. All water avenues through which typhoid fever could be conveyed to the military camp were efficiently guarded, and therefore a waterborne origin must be abandoned. But there was an epidemic of the fever raging among the prisoners of war, and guard huts surrounded the prisoners' lines and were close to them. This was unavoidable for military reasons. Those on sentry duty, in close contact not only with the prisoners, but with their latrines, urinals, and washhouses. The guards were exposed to the emanations arising from the latrines. Assuming that such emanations contain typhoid organisms, and also that typhoid infection can be airborne, the probability of the infection being borne in this way, appears to be well founded. Besides this, the soil of the enemies' camp gave peculiar facilities for the spread of the infection. It became very dusty after the camp had been established for a short time. The last point mentioned is the presence of almost a plague of flies in the camp of the enemy. These insects are well adapted for carrying infection, and there was nothing to prevent them from conveying the poison from one camp to the other. Although the writer believes that epidemics of typhoid fever are chiefly waterborne, in the present instance he believes it to have been airborne.

Münchener medicinische Wochenschrift, February 4, 1902.

Myelopathic Albumosuria.—T. R. Bradshaw has given this appellation to that form of albumosuria characterized by the presence of the so-called Bence-Jones' bodies in the urine. He opposes the statement of Jochmann and Schumm that this form of albumosuria can occur in osteomalacia, but believes it to be pathognomic of bone and marrow lesions, entirely dissimilar to those observed in this disease. The case reported by Jochmann and Schumm as one of osteomalacia, in which this form of albumosuria was present, is to be regarded as one of multiple myeloma, both from its clinical history and its autopsy findings.

Treatment of Pulmonary Hemorrhage by Subcutaneous Injections of Gelatin.—Ludwig Thieme is enthusiastic in regard to the value of this treatment for pulmonary hemorrhage. He reports its use in twelve cases, upon the results of which his opinions are based. This method should not be considered as a last resort in the treatment of this condition, but should be employed in all cases in which the hemorrhage is at all severe, even before other remedies have been tried and found wanting. In Thieme's experience no considerable local disturbance has been produced at the site of the inoculation. Sodium was always added to the gelatin solution before injection. The swelling following the inoculation was gently massaged and an aseptic dressing with iodoform gauze applied. Two cases in which these precautions were not observed showed more marked local disturbances than the others. As a rule, fever follows the inoculations. In some cases it lasts for four or five days, and the evening temperature may reach 40.3°–40.7° C. (104.5°–105.2° F.). All the inoculations were made into the outer surface of the thigh. One hundred cubic centimeters was the quantity uniformly introduced at one sitting.

Taxis in Incarcerated Hernias.—Otto Lanz is strongly opposed to the use of taxis in the treatment of incarcerated hernias. He believes that at the present day, in consideration of the great advancements in aseptic abdominal surgery, herniotomy is by far the most preferable procedure. The injury to the intestine and contiguous structures, brought about by taxis, even when this is successful, is often so extensive that serious consequences and frequently even death result therefrom. A case is recited in illustration of this fact. Also apparently successful taxis often effects reduction in mass without the incarcerated gut being freed, and it is important to comprehend that this result may be brought about with the employment of very little force. In these cases the symptoms, of course, persist, and a subsequent operation, which must be much more extensive than herniotomy, is rendered necessary. Taking into consideration all these facts, the author believes that in all cases of incarcerated hernia primary herniotomy is the best procedure. In every case the hernial sac should be opened before reduction and the condition of the intestine ascertained. Local anæsthesia is preferably employed, and for this a one per cent. cocaine or Schleich's solution should be used.

Treatment of Chronic Middle-Ear Catarrh by the Pneumatic Chamber.—Hamm reviews the methods of treatment commonly in vogue for chronic middle-ear catarrh with adhesions. All of these methods have for their aim the breaking down of the adhesions by mechanical means. All yield unsatisfactory results, and it is seldom that benefit is derived therefrom. He reports his results in the treatment of eight cases of this trouble by means of the pneumatic chamber. Of these, in three the hearing was materially and permanently benefited. In all there was temporary improvement. The author, himself, was one of those who received permanent benefit. The pressure employed in the pneumatic chamber or cabinet may be from ½ to 1½ atmospheres. One atmosphere seems to give the best results. The duration of each treatment should be an hour and a half. Of this time time 25 minutes is consumed in gradually increasing the air pressure and 40 minutes in gradually reducing it. Twenty-five to forty treatments are necessary in order to determine what result is to be obtained. The acuteness of hearing during the sittings varies in different cases. In some cases it is greatly accentuated, while in other cases it is reduced. If the benefit is permanent following the cessation of treatment a series of sittings should be given at yearly or half-yearly intervals in order that relapses may be averted. The most that can be said for this treatment at the present time is that it benefits a few cases which are not influenced by other methods.

Berliner klinische Wochenschrift, January 27, 1902.

Symptomatology and Therapy of Chronic Pulmonary Emphysema (Vagus Neurosis).—F. Riegel refers to the recent article by Zuelzer in regard to chronic pulmonary inflation (see abstract MEDICAL RECORD, January 18, 1902). The direct connection between pulmonary inflation and the vagus was first communicated by the author in conjunction with Edinger in 1882, as the result of experimental researches with respect to asthma. Since that time Riegel has uniformly administered atropine in chronic pulmonary emphysema, and also in all other conditions in which over-stimulation of the vagus was the causative factor in the production of symptoms.

Prognosis in Glaucoma.—Fritz Mendel reports the results obtained in the treatment of 258 glaucomatous eyes in 234 patients. In fifteen no operation was undertaken, and of these nine were treated by eserine. Instillations of physostigmine were used in eight cases with good result, so that operative treatment could be deferred. Iridectomy was performed 216 times. In eight of these cases the glaucoma was bilateral. One eye was entirely blind and the other partially so In these cases the operation upon the blind eye not only relieved the pain therein, but the condition in the other eye was materially improved. Sclerotomy was performed twelve times, and enucleation thirty-one times. In the various forms of glaucoma treated by iridectomy, the following results were obtained: In acute glaucoma 64.4 per cent. were cured, 17.8 per cent. greatly benefited, while 9 per cent. remained *in statu quo*. In chronic inflammatory glaucoma 25.7 per cent. were cured, 51.4 per cent. improved, and 17.1 per cent. not benefited. In simple glaucoma 4.6 per cent. were cured, 71.2 per cent. improved, and 19.5 per cent. not benefited. In cases complicated by secondary increase in tension 20.4 per cent. were cured, 29.6 per cent. improved, and 12.9 per cent. not benefited. Hereditary glaucoma was observed nine times. In two instances benefit in vision was obtained by this treatment. It is thus seen that iridectomy is the treatment *par excellence* for this disease.

—*Berliner klinische Wochenschrift*, February 3, 1902.

Tympanites.—M. Falcoz says that tympanites hysterica is caused by a contraction of the diaphragm, which is permanent in character, although it may be but slightly marked and demonstrable with difficulty on physical examination of the lungs. Partial tympanites, giving rise to a circumscribed tumor, may result from the same cause [illegible] a partial transverse contraction of certain abdominal muscles and a laxity of others. The [illegible] abdominal phantom tumor recently reported by Lenhartz is to be considered of same genesis. Falcoz reports a somewhat similar case which is to be considered in the same light. These tumors may appear as part of the symptom-complex of hysteria or they may be the sole manifestation of this disease. The reason why certain cases of hysteria should show contractions only in the diaphragm and certain abdominal muscles is somewhat obscure, but it seems probable that these are produced [illegible] as the result of stomach distention.

History of the Westphal-Piltz Pupil Reaction.—Meyerhof says that Westphal and Piltz are in no way to be considered as the discoverers of the pupil phenomenon. The fact that it is present in certain conditions and is of diagnostic importance has been previously mentioned by several other authors, such as Galassi in 1887, Wundt in 1880, Ragel in 1885, and Mulh in 1883. The first, however, to describe the phenomenon was A. v. Graefe, in 1854. He not only mentioned its diagnostic importance, but advocated its therapeutical use in the treatment of immovable pupils. Graefe's idea was that the pupil movement is complementary to the movement of the orbicularis muscle of the other eye. It still to-day seems certain that this view is correct. Several authors hold that the phenomenon is brought about as the result of pressure of the lid as it closes over the eye-ball. This view is disproved by the following facts:—(1) If the eye is closed but the lid held away from the eye-ball so that it exerts no pressure thereon, the phenomenon is easily produced; (2) Pressure with the finger directly upon the eye-ball fails to elicit the reaction; (3) Pressure upon the eye-ball does not cause congestion of the blood-vessels of the iris, as has been claimed; (4) Experimental researches have shown that congestion of the blood-vessels of the iris does not produce myosis.

An Artificial Œsophagus.—Siegfried Spiegel reviews the various methods of treating stricture of the œsophagus, and shows that in many cases the ordinary method of dilatation by sounds gives unsatisfactory results. The method of feeding directly through an artificial gastric opening is not well borne by most patients, and experience has shown that in most cases weight and strength are progressively lost when such feeding is resorted to. This is very largely due to the fact that the appetite is practically lost and the process of digestion is without the normal stimulation arising from mastication. The action of the saliva, which in a measure prepares the food for stomach digestion, is also entirely wanting. In order to overcome these failings the author has devised an artificial œsophagus. He exhibits several varieties which differ slightly in their mechanical construction. The essentials of the apparatus consist of a tube of sufficient length to reach from the upper portion of the œsophagus to the middle of the stomach, the distance being measured on the outside of the body. This tube is provided with an appliance which facilitates the passage of food downward, and also with a suitable contrivance at both ends for making it fast and continuous with the artificial apertures. Two permanent artificial openings are made, one in the upper portion of the œsophagus above the stricture and the other in the anterior wall of the stomach and abdomen. The superior extremity of the tube is made fast to the œsophageal and the inferior to the gastric opening, the body of the tube lying on the chest wall outside of the thorax. By the use of this artificial œsophagus the patient can masticate and swallow food in the ordinary manner. It can be worn continuously throughout the day and taken off before retiring if desired.

French Journals.

Discovery of the Plague Bacillus in the Proboscis of a Mosquito.—While La Bonnardière and Xanthopoulides of Beyrouth were attending a patient, one of them was bitten on the cheek by a mosquito. They caught a mosquito in the room and, on examination, found that it was gorged with blood. In the proboscis were several microbes, which were clearly recognizable under the microscope as those of plague. There was no opportunity at the time of inoculating an animal with these.—*Le Bulletin Médical*, January 29, 1902.

Nephrotomy in Chronic Medical Nephritis.—Pousson calls attention to the cause of nephritis as being a disturbance in the circulation of the kidney. In the last three years he has operated on six patients with Bright's disease. At least one of these cases can be considered cured. This patient had severe symptoms of the disease and medical treatment had produced no results. The writer operated, after which the quantity of the urine increased as well as the amount of urates and other salts. There now exists only a trace of albumin, and the various other elements of the urine are normal in quantity. Another patient had symptoms of subacute Bright's disease, with considerable œdema and grave cerebral symptoms. Unilateral nephrotomy was done. From the third or fourth day after the operation the œdema of the side operated on disappeared. At the end of twelve days it disappeared from the other side. Some albumin and casts are still found in the urine, but the relief is considerable.—*Journal de Médecine de Bordeaux*, [illegible]

Lavage of the Intestine in the Child.—M. L. Balestre states that some of the effects of this treatment are mechanical—a thorough cleansing of the intestinal mucosa. Others are physiological—a stimulation and regulation of the peristaltic movements of the intestine and excitation of the secretion of the glands of the digestive tube, and especially of the liver. As to the indications for lavage of the intestine, they vary with circumstances. Many authorities extol it in cholera infantum and dysentery. In acute febrile gastroenteritis lavage of the intestine with cold water is indicated. It lowers the temperature of the body and diminishes intestinal fermentation. In cases in which the stools are extremely fetid, it is especially valuable. In those forms of chronic gastroenteritis in which the intestinal symptoms predominate, this treatment is most useful. The phenomena of intoxication are often markedly ameliorated. In older children the method is equally successful. Lavage is also indicated in intestinal occlusion. The only contraindication to lavage of the intestine, as in the case of lavage of the stomach, is collapse.—*Gazette des Hôpitaux Civils et Militaires*, January 28, 1902.

Bony Ankylosis of the Temporo-Maxillary Articulation, Following Traumatism.—M. Tendlus speaks of this affection as being most rare. It manifests itself generally between the ages of fifteen and twenty years. The ankylosis is generally unilateral, although cases of double ankylosis have been reported. Irreducible dislocations may give rise to this trouble; also fractures of the neck of the condyle, and especially fractures of the walls of the glenoid cavity. Traumatic arthritis may also be the starting point for this trouble. These are only a few of the causes of this serious affection. The prognosis of ankylosis of the jaw is grave, from the fact that it hinders or prevents mastication and renders normal digestion impossible. Nutrition is compromised and serious results follow. Numerous operative proceedings have been proposed by different authorities. The writer concludes that a serious traumatism of the temporo-maxillary articulation occurring at an early age is always followed by bony ankylosis. Ankylosis is favored by the proliferation of a very active periosteum. Surgical treatment is justifiable, the best method being the resection of the condyle and, if necessary, the resection of the coronoid apophysis. The success of the result is proportional to the size of the piece of bone which is removed.—*Revue Médicale de la Suisse Romande*, January 20, 1902.

Some Observations on Epidural Injections.—A. Chipault sums up his personal experience with epidural injections as follows: As a method of producing surgical anæsthesia, it gives results too inconstant to justify its introduction into common practice. As a method of producing medical analgesia it is worthy of a place in therapeutics. In neuralgia and in neuritis it seems to possess an efficacy superior to most of the medicinal means employed. It is of the greatest service also in tuberculous and cancerous lesions of the vertebræ, especially when the inefficacy of the ordinary methods of treatment is considered. This epidural injection produces, sometimes from the very first, a lasting effect; more often, however, especially in the affections last mentioned, it has to be repeated, and while the first injection gives a fleeting or negative result, a second, and especially a third, produces relief which continues for a long time, and which sometimes is permanent. The solution which appears to be most practical is that of chlorhydrate of cocaine in the proportion of 1 to 100. Considered as a topical therapeutic method its future seems very limited. It can be used only in lesions in the epidural space, excepting in cases of tuberculosis of the sacral or lumbosacral region which are particularly resistant to the treatment by immobilization—so successful in tuberculosis of the upper parts of the vertebral column; in these lower lesions it is legitimate to give epidural injections of glycerin and iodoform. The epidural method has indications very different from those of the sub-arachnoid method.—*La Tribune Médicale*, February 5, 1902.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 10, 1902.

John B. Walker, M.D., Chairman.

Urinary Bladder in an Inguinal Hernia; Radical Operation Under Spinal Anæsthesia.—Dr. Willy Meyer presented a man sixty years of age, who had entered the German Hospital the middle of last June on account of a large, right inguinal hernia. It had troubled him since 1888, and had at last become irreducible and so large as to prevent him from walking. Physical examination showed a very marked diffuse bronchitis, and because of this the radical operation was done under spinal anæsthesia. The analgesia was perfect. On opening the sac it was found to contain the greater portion of the omentum, and this was removed by ligating it in sections and amputating these. A peculiar mass was found situated on the inner side of the sac, which was thought to be a vesical hernia. The separation of the tissues was, therefore, conducted very carefully, but despite this, the mass was injured, and a gush of urine confirmed the suspicion that the bladder had been opened. The wound in it was closed with two rows of sutures, one row being of silver. A continuous suture was then inserted at the neck of the sac, an opening one and one-quarter inches in diameter being left for gauze drainage. A catheter was not left in. There was no reaction following the operation, and forty-eight hours later he was again anæsthetized by the same method. The analgesia this time was also perfect, and it enabled the operator to complete the operation by doing a regular Bassini operation. Recovery was uninterrupted, but the man was kept upon his back for six weeks in order to relieve the operative field from abdominal pressure. He was discharged in perfect condition, and was advised not to wear a truss. When next seen, in December, he stated that there had been a slight recurrence of the hernia in the lower portion of the wound, apparently induced by his coughing. This recurrence took place exactly where the vesical hernia had been pushed back. The patient was now wearing a truss, and was perfectly able to continue his occupation of carpenter. Dr. Meyer said that this case seemed to be of the combined form in which the bladder is situated, both intra- and extraperitoneally. According to statistics, this complication of inguinal hernia was found in about 1 per cent. of the cases. Perhaps no other operation demonstrated so well the possibilities of spinal analgesia. He had used tropacocain in fifty cases, and had been pleased with its action. Spinal analgesia should only be employed under strict indication.

Dr. H. Lilienthal said that ten years ago he had assisted Dr. A. G. Gerster in an operation on a case of hernia. A mass was found during the operation, which was taken to be a hydrocele and was opened deliberately. It proved to be the urinary bladder. The patient recovered without incident. In the next case of the kind that he had seen the patient was suffering agonizing pain, although the tumor had only been down a few hours. The man was able to pass urine, and was catheterized before the operation, but the tumor was found to be just as tense as before the use of the catheter. Suspecting that the bladder might be in the hernia, the operation was proceeded with cautiously, and the radical operation done. The bladder was found in the hernia. Recovery was uneventful. One of the internes of the hospital had recently operated upon a non-strangulated hernia, and had accidentally opened the bladder, which was found to be a part of the hernia. The rent was sewed up, and a Bassini operation done, and the patient recovered without any complications.

Dr. Fred Kammerer said that, in the first case of this kind that he had encountered, he had failed to recognize the bladder. The organ was almost empty at the time it was opened. The rupture was sutured and a Bassini operation done, but the patient died of sepsis. In the second case the bladder was recognized, and there was no untoward result. Regarding cocainization of the spine, the speaker said that he had been among the first to use it extensively. In a former paper he had stated that this form of anæsthesia was only indicated when other methods were out of place, and he desired to reiterate this because spinal anæsthesia had been employed enthusiastically and indiscriminately for a long time, and had caused a revulsion of feeling, so that of late the method had been somewhat neglected. He had been surprised to note how well old and feeble persons stood spinal anæsthesia.

Dr. C. L. Gibson said that he had seen a number of cases of hernia of the bladder, and for this reason had written a paper on the subject at one time. He thought he had seen the bladder in hernia operations about ten times, though a number of these cases were not really examples of hernia of the bladder, but rather of a displacement of this viscus, produced artificially by pulling it up during the manipulations incident to the operation.

Dr. A. A. Berg asked Dr. Meyer if he would consider a hernia operation one of the indications for spinal anæsthesia.

Dr. John B. Walker said that he had seen an operation for femoral hernia in a woman in which the bladder had come into the field and had been incised. The wound was sutured and drainage employed, and the patient made a good recovery. The same thing had occurred in a male during an operation for inguinal hernia, and recovery had been equally good.

Dr. Willy Meyer said that there must have been a large diverticulum in his case, because the cavity was examined with a probe at the time, and the latter entered it for a considerable distance. A large quantity of urine escaped from the opening into the operation wound, and as the sac had not yet been closed, he was afraid to go on with the hernia operation lest the urine might have caused infection. The majority of surgeons had avoided using a catheter in these cases, and this seemed to be the better practice. In his opinion, a herniotomy would be an indication for spinal anæsthesia if there were any reason for not employing the more usual methods of inducing anæsthesia. He had made use of spinal analgesia in various bladder and prostate operations on old people, and with most satisfactory results. The spinal analgesia injection was frequently followed by chill and high fever, and as these symptoms occurred after some urethral operations, the true condition of the patient might be obscured for a time.

Carcinoma of the Stomach; Gastroenterostomy; Occlusion of Murphy Button.—Dr. A. V. Moschcowitz presented a man, sixty-six years of age, who had been admitted to the Mount Sinai Hospital on July 15, 1901. He had lost flesh rapidly, having fallen from 140 to 75 pounds, and complained of pain in the stomach and of frequent vomiting. On examination a movable tumor was found above and to the right of the umbilicus. The stomach was dilated, and its contents showed a total acidity of thirty, an absence of free hydrochloric acid, and the presence of butyric and lactic acid On July 26 Dr. Gerster operated upon him, and because of his bad condition, local anæsthesia was employed. It had been intended to do a pylorectomy, but the man's condition was so feeble that a posterior gastroenterostomy was done and a Murphy button inserted. After the operation the patient did well up to August 13, or nineteen days after the operation, when he began to vomit without apparent reason, and went into collapse. The vomiting remained uncontrollable in spite of lavage and rectal alimentation. He was operated upon at once for the removal of the button, and the latter was found at the site of the anastomosis occluded with food. The button was removed, and the [illegible] at [illegible]. According to Dr Reginald H. Fitz of Boston, statistics showed the operation of gastroenterostomy to be of no value. But this man had lived now for nearly eight months in practically perfect condition, despite the fact that death from starvation seemed imminent at the time of the first operation. His weight was now 142 pounds.

Dr **Kammerer** spoke in favor of making as small an opening as possible, forcing in the segments of the button and fastening the latter, but avoiding the purse-string suture, which, he thought, caused a puckering and made pressure unevenly on the tissues. If a Murphy button pressed well against the walls of the two viscera it should come away after six or seven days. In quite a number of gastroenterostomies he had never experienced any trouble after using this method.

Dr **Walker** said that he had tried this plan and felt sure that it was easier and superior to the purse-string suture.

Dr. E. M. **Foote** said that the method advocated by Dr Kammerer was no guarantee that the button would not stay in the stomach, as he could testify from personal experience. Mention was made of one case in which it had remained for months.

Dr **Lilienthal** said that he would agree with Dr Moschcowitz that Dr Fitz was wrong in asserting that this operation of gastroenterostomy was one unworthy of surgery. The experience detailed by Dr Fitz was certainly not that of most surgeons, and there was surely a place for this palliative operation.

Dr **Meyer** said that he had done gastroenterostomy upwards of twenty times, and always made use of the purse-string suture after the method advocated by Murphy. So far, he had had no trouble. In one case the button dropped into the stomach, and its presence there was demonstrated by means of the *x*-rays. The man had been seen since, and was in good health, although the button was still in his stomach. Last year he had presented to this Section a patient upon whom he had used the elastic ligature, according to McGraw's method. This was a most valuable procedure, and he was sure those who gave it a trial would continue to use it in cases of both anterior and posterior gastroenterostomy in connection with the lower gastrointestinal tract. It was both a simple and safe method.

Dr **Kammerer** said he did not mean to say that good results could not be obtained with the purse-string suture used by Murphy, that the method to which he had alluded, and for which he had expressed a decided preference, seemed better adapted for securing the necessary uniform necrosis. In the case referred to by Dr. Foote it was probable that the button was of faulty construction.

Dr. A. A. **Berg** remarked that in these cases the button should be a new one, and should be provided with a specially strong spring.

A Method of Preserving Gall-Bladder Specimens.—Dr H. **Lilienthal** presented a gall-bladder and stone removed from a man of fifty-two about three weeks and a half ago. The patient had suffered from attacks of colic and jaundice without much fever. Recovery had been prompt. In this connection Dr Lilienthal presented a gall-bladder which had been turned inside out and stuffed with cotton, and sewed up. A specimen prepared in this way showed the internal surface of the gall-bladder and the changes which had occurred as a result of inflammation.

Clinical Memoranda in the Study of a Case of Anuria.—Dr A. V. **Moschcowitz** reported this case. The patient, a woman, had been admitted to hospital on March 15, 1901, while pregnant. She gave a history of previous malarial infection, also of sudden abdominal pain on the left side, followed by a sharp chill. Her physician had catheterized her twice, but had succeeded in withdrawing only a few cubic centimeters of non-urinous fluid. The left lumbar and left hypochondriac regions were the seat of a [illegible] tumor. Only 4 c.c. of fluid were withdrawn by catheter, and the fluid was smoky in appearance and contained pus cells, albumin and just a trace of urea. Dr Moschcowitz operated at 1 A.M., doing a double nephrotomy with a view to relieving the congestion of the kidney. The right kidney had been converted into a large purulent hydronephrotic sac, while on the left side there was only a small abscess cavity. The case was one of complete suppression of urine of three days' standing. Owing to imperfect drainage of the abscess cavity, the patient did not do well, and consequently on March 18, or twelve days after the operation of nephrotomy, nephrectomy was done on the right side. On March 21 the patient for the first time passed urine voluntarily, but it was ten days more before she passed urine regularly in the natural way. From a careful study of the case after operation, he had been led to conclude that the anuria had resulted from a bending of the ureter by the pressure of a floating kidney. Cases of anuria had been reported in which only one ureter had been blocked by a calculus. Such cases were described as reflex anuria, and the existence of this form of anuria had been demonstrated experimentally. There were undoubtedly a few cases on record in which the condition had been relieved spontaneously, but this result was so very exceptional that no argument seemed necessary to show that the treatment must be surgical. Nephrotomy was demanded to meet the immediate indication.

Dr Moschcowitz said that since writing this paper he had had another case of anuria. The man entered the hospital with a tumor on one side of the abdomen. He had passed no urine for twenty-four hours. Nephrotomy on the left side was done, and a large cystic kidney found. There were numerous calculi in the parenchyma of the kidney. The suppression of urine persisting, the patient was again operated upon, a nephrotomy being done on the other kidney. It was then found that the kidney spoken of as cystic was really an example of cystic degeneration of the kidney. The secretion of urine was very scanty, and the patient eventually died.

Dr W. **Meyer** spoke of a remarkable case in which both kidneys had been diseased, necessitating at first removal of one kidney, and later of nephrotomy of the other kidney for anuria. The patient recovered perfectly and had remained well.

Dr. **Kammerer** recalled a case of calculus pyelitis from which a large stone had been removed, and two or three months later nephrectomy had been done. Two years after this the patient was seized with an acute anuria, which lasted sixty hours or more. Dr. Kammerer operated, doing a nephrotomy on the remaining kidney. The ureter was laid bare for twelve cm., and a stone found. The kidney was drained, and the patient was at present alive and well, eight years after the operation.

A Case of Actinomycosis; Resection of the Sternum.—Dr. A. A. **Berg** presented a boy who had been admitted to the Mount Sinai Hospital with a history of a swelling having developed at the right side of the sternum about two months previously. Coincident with the appearance of this swelling the boy lost flesh and strength, and had a variable temperature. On admission, the swelling was found to be fluctuating, and was supposed to be a cold abscess connected with one of the costal cartilages. On aspiration, a thick, yellowish mucopurulent material was withdrawn, and microscopical examination showed the presence of actinomycosis. For several weeks it was injected with a 10 per cent. solution of iodoform and ether, but the abscess showed absolutely no tendency to heal. The abscess was then freely incised and the costal cartilages of the third, fourth and fifth ribs removed, leaving the perichondrium intact. The boy improved a little, but the discharge remained rather profuse. Later the abscess was cut down upon again and the sinus followed. This necessitated the removal of the sternum with the exception of the upper portion and the xyphoid cartilage.

The perichondrium was left. It was found that the source of the suppuration was a gland behind the sternum. The broken-down material was curetted away and the wound packed. The healing process since then had been rapid, and the boy had gained about thirty pounds.

The Disadvantages of Gauze Packing, Particularly in Appendicitis Work.—Dr. Robert T. Morris presented a brief paper with this title. He said that Tait himself had not understood why so many more of his patients recovered than the patients of contemporary surgeons, but the secret had been discovered since then. Tait operated rapidly with as little disturbance of the parts as possible, and as a result his patients, not having lost their natural resistance, were capable of manufacturing phagocytes. If a patient were subjected to much shock these phagocytes would not be manufactured. The introduction of gauze packing produced such shock. The speaker affirmed that gauze packing was to-day unnecessary in abdominal surgery in cases of the widest possible infection of the peritoneal surfaces. The use of gauze packing represented a transition stage in our knowledge of the methods of treating septic abdominal cases. Surgeons had been loath to give up the gauze packing, and had been very conservative because they felt that such a radical change in technique might jeopardize life. The statistics of surgeons who had discarded gauze packing were not, however, at all the statistics of mild cases. It would not be safe to teach that gauze packing could be entirely discarded in abdominal surgery at once, but certain it was that iodoform gauze could be dispensed with. There were many hospital cases called septicæmia, which were nothing more than cases of incipient iodoform poisoning. The differentiation of these cases was to be found in the fact that in the cases of iodoform poisoning the wound looks well and the patient does not, whereas in cases of true septicæmia the wound also looks badly. Again, if the urine of a patient suffering from iodoform poisoning were mixed with calomel, the reaction indicative of the presence of iodine would be obtained. Iodoform, then, could be dispensed with to advantage, and the gauze packing should be gradually used less and less.

Dr. Thomas H. Manley asked Dr. Morris what he would substitute for the gauze packing. He thoroughly agreed with him regarding the inadvisability of using iodoform.

Dr. Carl Beck said that he had used iodoform very freely since 1878, but had not yet met with one undoubted and demonstrated case of grave iodoform poisoning. There was no doubt that in all cases in which iodoform was used iodine could be found in the urine, but this did not prove that the iodoform was producing any disastrous effect any more than it would in the case of a syphilitic who was taking iodide. It had long ago been shown that while iodoform was apparently inert when in contact with dead tissues, it was an exceedngly active antiseptic when employed in connection with living tissue. He had recently observed a case in which on the necrosed portions of tissue the iodoform was found unchanged at the removal of the dressing, while on the granulating areas it had disappeared. He thought it was unsafe to entirely dispense with gauze, either plain or iodoform gauze, though admitting that gauze packing predisposed to hernia.

Dr. Charles N. D. Jones said that Dr. Morris had made the statement that Mr. Tait did not know the cause of his success, yet this was not strictly true, because Mr. Tait avoided the use of bichloride and other antiseptics well known to be dangerous and harmful. He agreed with Dr. Morris that gauze packing should be avoided in the abdominal cavity. He had found that sterile gauze became infected in septic cases within twelve hours, while formalin gauze would remain sweet for about twenty-four hours. The insoluble citrate of silver seemed to him the best packing, as it would remain without odor for a week or ten days, and he had never observed any ill effects from its use.

Dr. A. A. Berg said that the position taken by Dr. Morris that gauze packing was hurtful by preventing the formation of phagocytosis was interesting, but its correctness yet remained to be proved. It was well known that the serous membranes could take care of a small quantity of mild sepsis, provided their function had not been interfered with. Where the surface had been injured material would stagnate on the serous surface, and drainage would be required. The question of whether drainage could be dispensed with depended upon the intensity of the infection and whether or not the serous membrane was in a healthy functionating condition. Iodoform should be avoided as far as possible, and from the experience at the Mount Sinai Hospital this seemed to be entirely feasible.

Dr. Martin W. Ware said that the indication for gauze drainage as for the use of drainage tubes was to satisfy local mechanical conditions. Phagocytosis was only a theory. Phagocytosis could be excited by leaving a sponge or a piece of gauze in the peritoneal cavity.

Dr. Lilienthal said that he was positive that iodoform poisoning occurred with sufficient frequency to warrant the surgeon in being much more careful than in the past regarding the use of this agent. He had seen fatal cases of iodoform poisoning, and other milder ones resulting only from the use of an almost insignificant amount of iodoform gauze. In one of the latter class of cases the patient complained for a long time of the taste of iodoform, and emaciated rapidly, but the nature of the trouble was not recognized until the appearance of an eruption.

Dr. Morris, in closing the discussion, said that he thought gauze packing could be done away with in most cases of abdominal surgery. His personal preference was for the use of a small wick drain connected with a large mass of gauze outside of the abdomen. The plan of closing up the abdomen completely had been first proposed by Clark, but other surgeons had followed in that surgeon's footsteps, and were getting good results without drainage even in markedly septic cases. There would always be some cases which must be drained, as, for example, those in which there was considerable oozing after the separation of extensive adhesions. From the theoretical standpoint, the objections raised by Dr. Berg seemed to be well taken. At one time he would have agreed with Dr. Berg that when the surface of the peritoneum no longer appeared healthy and its lymphatics active it would be risky to close the cavity without drainage, but he could no longer accept this view, for, at the present time, he found very few cases in which the peritoneum was not able to drain itself. It had been stated by Dr. Ware that the theory of phagocytosis had not been proved. To this he would reply that it had been proved empirically, and that it was not local phagocytosis but general phagocytosis that was needed.

An Aid to Cocain Anæsthesia—Rubber-Tired Scissors.—Frederic Griffith, having noticed that persons being operated upon under cocain anæsthesia were greatly annoyed and excited by the clicking noise made by the surgeon's scissors, has devised a rubber buffer by which this noise is deadened, though not interfering with easy sterilization of the scissors. He exhibited the device.

Pneumotyphoid Fever.—W. E. Sheperd reports three cases of fever to which he gives the name pneumotyphoid. By this term is meant a condition in which the typhoid bacillus seems to exert its baneful influence especially upon the pulmonary parenchyma, producing symptoms that are practically identical with those of croupous pneumonia. Clinically, the cases presented the features of rather prolonged pneumonia with a diarrhœa and rose spots on the abdomen. The treatment was essentially a stimulating one with oxygen inhalations. In fact, so far as the histories go, the cases might have easily been mistaken for pneumonia with that septic condition of the bowels sometimes found in this disease, and which is accompanied by erythematous patches on the skin.—*American Practitioner and News.*

NEW YORK ACADEMY OF MEDICINE

SECTION ON PEDIATRICS

Stated Meeting Held February 13, 1902

ROWLAND G. FREEMAN, M.D., CHAIRMAN

Acquired Syphilis in a Girl of Eight Years.—Dr. [illegible] WHITAKER presented a girl of eight years with acquired syphilis. Her previous health had been good. The history of the present trouble dated back about seven weeks. While in the bath a sore was noticed on the genitalia, and the child complained of frequent and painful micturition. On examination, the clitoris was very greatly enlarged and in the deeper parts of this swelling was a distinct induration. There was enlargement of all of the lymph nodes throughout the body, but most marked in the inguinal region. The epitrochlear and postauricular nodes on both sides were decidedly enlarged. At present there was a macular syphilide on the body, and inspection of the mouth showed the presence of mucous patches.

Stomatitis Due to the Bacillus of Vincent.—Dr. H. HEIMAN presented two children suffering from this form of ulcero-membranous stomatitis. The bacillus of Vincent and the spirillum of Muller were found constantly associated with this variety of stomatitis. A smear from the ulceration made on a cover glass and stained with carbol fuchsin would show the characteristic bacillus. The treatment consisted in the application of a 5 or 10 per cent. solution of nitrate of silver, and a mouth wash of permanganate of potassium.

The Pathology of Adenoids and of the Tonsils.—Dr. A. J. LARTIGAU read this paper. He said that, the presence of lymphoid tissue with irregular depressions and the lack of epithelial covering in some parts made infection easy, and it was also favored by the traumatisms to which the tonsils were exposed. Regarding tubercular infection of the tonsil, he said that it might occur as a primary or a secondary lesion. The latter was found in over 80 per cent. of the cases of advanced pulmonary tuberculosis. On other hand, primary tuberculosis of the tonsil was rare. The tuberculous lesions were usually few and focal in character. The only accurate results in this field of research had been obtained by animal experiments.

Operative Treatment of Adenoids and Enlarged Tonsils.—Dr. W. K. SIMPSON read this paper. He said that, strange as it might seem, there were still some who, for various reasons, were opposed to operation on adenoids and enlarged tonsils. In his opinion, all hypertrophied tonsils and adenoids in children sufficiently large to produce symptoms should be surgically removed. He was convinced that adenoids were responsible for more ills in childhood than any other one common pathological condition. Among the disorders arising from the presence of pharyngeal adenoids were repeated attacks of coryza, chronic rhinitis, arrest of nasal development, nasal stenosis and mouth breathing with the associated mental listlessness; a tendency to attacks of spasmodic croup, asthma and bronchitis. It was also almost the sole cause of middle ear deafness in cases of acute suppurative otitis media. A digital exploration should always be made before operating. The curette and forceps were the instruments needed for the removal of the adenoids; the use of the finger for this purpose was mentioned only to be condemned. The choice between the curette and the forceps was a matter of individual preference. He personally preferred the forceps, because it would bring away a larger mass and the operator could see how much had been removed. With the curette the portion removed was apt to be lost and might even drop into the larynx. In small children the curette was probably the safer instrument. The forceps should be strong, large enough to conform to the shape of the nasopharyngeal vault, and have sufficient cutting surface, and should be so protected as not to do harm to the uvula or the posterior border of the soft palate. The principal fault with the older type of forceps, represented by the Lowenberg forceps, was that the cutting surface was too small, necessitating repeated introductions. It was exceedingly difficult to exactly locate a small instrument in the nasopharynx, and hence he preferred a larger forceps. A very useful type of forceps was the Gradle, particularly as modified by [illegible]. This forceps has an extensive cutting edge, and hence tearing was not necessary. When the operation was to be done without an anesthetic the child should be placed upright, and held by an assistant in the intubation position. A mouth-gag is used and the forceps are introduced, closed. They are then opened widely and pressed well upward and behind, the mass seized and the forceps withdrawn. The finger should always be introduced in order to determine the location and extent of any remaining masses. The latter might be removed with the finger curette or with smaller forceps. Occasionally only a small amount of the growth would be removed at the first attempt, because of a faulty adjustment of the instrument. The patient's head should be raised for a moment during the introduction of the instrument, then lowered and the child turned on the side to allow of the escape of blood. When the curette was used the position was the same. The curette should be chosen with a view to size and curve, these being determined by the age of the child and the situation of the growth. For those situated more on the vault and anterior, a curette with a marked forward curve would be required. The Gottstein curette, or some modification of it, was usually employed. The curette should be carried well up into the vault, carrying the soft palate forward, then it should be brought down with a bold sweep. Adenoids would recur in a small proportion of cases, probably because of portions having been left behind.

Tonsillotomy.—The bistoury was very seldom used in this country for doing the operation of tonsillotomy. Some operators made use of a wire snare on the supposition that there was less danger of hemorrhage, but the adjustment of the snare in a child was exceedingly difficult of accomplishment, and the danger of hemorrhage was not less. His personal preference was for some form of tonsillotome, the best, in his opinion, being that made by Ermold. He thought the little darts on the end of the fork should be dispensed with, as they often caught in tissues where they should not. The Mackenzie type of tonsillotome was also a very good one, because of its simplicity and strength. The instrument should be introduced and pressure made outward on the shaft while the assistant presses the tonsil inward from the outside. The instrument should be as small as consistent with grasping the tonsil, and great care should be taken not only to push the shaft of the instrument outward, but to maintain this pressure until the tonsil had been excised. Occasionally the tonsils were so adherent to the pillars of the fauces that they required separation with scissors or bistoury before excision. In a flat, broad or elongated type of tonsillar hypertrophy it might be impossible to encircle them with the tonsillotome. In such cases the tonsillar punch could be used to reduce the size of the tonsil, or galvano-puncture might be resorted to. The latter method was exceedingly tedious and troublesome. Tonsils, once properly removed, do not recur. The question of hemorrhage need not cause any anxiety. Hemorrhage of any gravity rarely, occurred after tonsillotomy in children. At the time of the operation the hemorrhage might seem rather profuse in some cases, but it usually ceased spontaneously. If, however, hemorrhage should occur, the operator should look for the bleeding point. If there appeared to be a general oozing, the application of peroxide of hydrogen or the galvanocautery or of a solution of adrenalin would probably answer every purpose, as would also the application of pressure. The use of suprarenal extract or adrenalin marked a distinct advance in the treatment of such cases. He had found adrenalin exceedingly useful in the removal of tonsils from older children and from adults. It should not be forgotten that after the use of suprarenal extract or adrenalin there was a possibility of secondary hemorrhage after the blood-vessels had regained their tone. Unless there were some marked indications, such as the appearance of sepsis or some unusual local condition, he thought it was better to do very little after the operation. Douching, spraying and the insufflation of powders should be forbidden except under strict indication; the vast majority of patients did better without any local treatment. The operation for the removal of adenoids left a very extensive wound, and the use of gargles, by causing undue motion of the throat, might cause hemorrhage. The swallowing of cracked ice at short intervals for the first twenty-four hours was excellent, as was also the application of ice to the throat externally. Confinement to the house and quiet should be enjoined, and it was well to have the patient sleep with the head high, in order to guard against hemorrhage. For several days after the operation the diet should be light, and such articles as crust of bread, dry crackers and pieces of meat should be avoided. Dr. Simpson favored doing tonsillotomy without anæsthesia, principally for the reason that by the motions gagging the operator was materially assisted in drawing the tonsil into view, and was much better prepared to control the hemorrhage after the operation. On the other hand, the operation for adenoids could be most thoroughly done under a general anæsthetic. It was desirable to have the child awaken quickly after the anæsthetic, and hence, many favored the use of the A.C.E. mixture, ethyl bromide or nitrous oxide, though his own experience had been solely with chloroform.

Recent Contributions on the Constitutio Lymphatica.—Dr. James Ewing read a paper with this title. He said that the lymphatic constitution was characterized clinically by sudden death of children, who showed: (1) General lymphatic hyperplasia; (2) Persistence of the thymus; (3) Hyperplasia of the aorta and sometimes of the heart; (4) Evidences of rachitis; (5) Evidences in their organs of retarded development; (6) Enlargement of the thyroid, and (7) General neurotic tendencies. It had been noted that the grand mal type of epilepsy occurred amost exclusively in persons showing the lymphatic constitution. Dr. Ewing said that in a former paper he had suggested that many sudden deaths, occurring in infectious diseases, were referable to this lymphatic diathesis, and since then several cases tending to confirm this view had been reported. In a large proportion of the cases there was enlargement of the thyroid. Recent observations had called attention to the presence of an atrophic stage of the lymphatic diathesis. The relation of the status lymphaticus to the various types of lymphatic tuberculosis demanded more attention than it had hitherto received. The essential danger in constitutio lymphatica was apparently the nervous disorder, and it should be noted that nervous symptoms were present throughout the course of the disorder. Laryngismus occurred frequently, if not exclusively, in persons of the lymphatic diathesis. Many cases of thymic asthma had been found to clearly belong to the lymphatic diathesis, and in some of these the enlargement of the thymus was certainly sufficient to give rise to pressure upon the trachea. There were, however, purely nervous cases in which no obstruction of the trachea could be detected other than that due to spasm. A most interesting question was the pathogenesis of the fatal symptoms That subjects showing hyperplasia of the aorta exhibited a diminished vital resistance had been proved by a large number of observations. The true explanation of the fatal issue was, however, yet wanting.

Danger of Chloroform in Children.—Chloroform was the anæsthetic which was commonly and almost indiscriminately employed among children, and yet it was well known that in cases of status lymphaticus chloroform is almost uniformly fatal. This question was assuming great importance, and since writing his first paper on this subject he had learned of about fifteen deaths in this class of cases—indeed, the opinion was gaining ground at the present time that chloroform was only fatal in this class of subjects.

Notes on the Surgical Treatment of Enlarged Lymph Nodes.—Dr. Charles N. Dowd was the author of this paper. He said that the treatment of enlarged lymph nodes, of course, depended largely upon the diagnosis. The main point was to differentiate between simple and tuberculous inflammation of these nodes, and this was often most difficult. His own opinion was that tuberculous lymph nodes should be removed as soon as the diagnosis had been made. He had operated quite extensively on such cases and without any fatalities. The incisions could be so placed as to be less disfiguring than the scars following abscess formation. Of the cases upon which he had operated, twenty-three had been apparently cured and forty-seven improved. In a group of ten cases, followed for from four to eight years, there were apparently eight cures. One German observer had reported 130 cases of thorough operation with 70 per cent. of cures, while in 167 cases without operation there were only 24 per cent. of cures.

Dr. A. Jacobi said that the question would always arise as to why so many of these conditions were found in children and not in adults. This was especially true of swelling of the tonsils and of the neighboring lymph bodies. One reason probably was that the lymph ducts had been found comparatively numerous and comparatively large in the young. Another reason was that adults suffered more because, as a result of inflammatory affections in early life, the tonsils were no longer soft, and hence not so vulnerable to microbic invasion. This was the principal reason why diphtheria was so very rare in the adult and so very frequent in the young. It was, of course, not impossible that a certain degree of immunity might be produced by reason of repeated attacks in early life.

Not All Adenoids Require Operation.—Regarding the treatment of adenoids, Dr. Jacobi said that when adenoids are large, they should be removed All were agreed on this point, but not so on the question as to whether operation was necessary in cases in which adenoids were small yet numerous enough to cause snoring. He was one of those who did not think these cases required operation. The cause of the chronicity of pharyngitis, rhinitis and rhinopharyngitis, of swelling of the tonsils and secondary laryngitis, was almost always a local catarrh, which, if recognized, had not been appreciated at its full value. The treatment was very simple, and consisted in irrigating the parts twice daily with saline solution or with a solution of boric acid. A large experience, extending over a great many years, warranted him in positively expressing the opinion that this simple treatment would not only prevent inflammation, but would restore to health many chronic cases. Irrigation by means of the cup would suffice, and, if it were generally adopted, would result in comparatively little need for operation. He found that it was the practice of specialists to carry out no after-treatment after operating upon adenoids. If they insisted that the parts should be irrigated and kept clean, there would be no relapses. He had never operated in these cases with an anæsthetic, for, no matter what anæsthetic was employed, it must be pushed in order to overcome the powerful masseter muscle. Such profound anæsthesia seemed to him dangerous. As a rule, the operation for adenoids was not difficult, and only one assistant was required. The operator should sit down and have the mother or assistant sit in a chair in front of him. The head of the child should be buried between the thighs of the operator. The Gottstein curette could be quickly introduced and the operation completed in a minute. This was a simple and easy way; he would not advise anæsthesia under any condition.

Dr. Francis J. Quinlan said that any kind of irrigation of the nasal chambers was very disastrous because of the forcing of the secretions into the middle ear. He would contend that all forms of lymphoid hypertrophy should be removed because what to-day was small and apparently innocent might by to-morrow be sufficiently large to obstruct the nasal passages. It seemed to him that these irrigations did absolutely no good, because they forced the secretions back to where they came from. These secretions came from the rhinopharynx only. When the lymphoid hypertrophies were allowed to remain they not only injured contiguous structures, but menaced even remote parts. The occurrence of snoring was no indication of nasal obstruction, because it often resulted from the dropping back of the tongue during sleep, or perhaps simply from the vibration of the soft palate.

Dr. Henry D. Chapin said that the laryngologists had been speaking of the severe forms of adenoids, while Dr. Jacobi had referred to the mild forms. He would agree with Dr. Jacobi that this latter class did not require operation. Only recently he had had a child under his care in whom the adenoids were becoming smaller under irrigations, yet a specialist had insisted that unless the operation were undertaken the child would become deaf or have some other dreadful affliction. Of course, all were agreed that the more severe cases should be subjected to operation.

Dr. W. K. Simpson said that the cases referred to by the last speaker as mild often proved to be the most severe ones in the end, quite probably from the occurrence of otitis media.

Dr. Chapin asked Dr. Simpson if he had ever known otitis media to follow the operation for the removal of adenoids.

Dr. Simpson replied that he certainly had met with such cases, and we all knew that persons had died from a splinter in the finger, but this was no argument against the treatment advocated.

Dr. Dowd said that what Dr. Ewing had said about the danger of giving chloroform to children should lead us to think seriously about revising the common practice here of giving chloroform to children. Why should this be done when it was customary to give ether almost always to adults? Chloroform was as dangerous to children as to adults; ether should be the anæsthetic of choice.

Dr. Jacobi said that the average child bore chloroform better because the average child, not the diseased child, had a stronger heart than the average adult.

Dr. E. Libman, referring to the cases presented earlier in the evening by Dr. Heiman, said that the bacilli found in connection with this form of stomatitis were not specific, as they had been found elsewhere; they seemed to be organisms found in connection with the destruction of tissue. It had not yet been proved that they were typical of any special disease. This form of stomatitis had been known for years under another name. One could not exclude syphilis if these organisms were present, though diphtheria could be ruled out.

Septic Eczema; Pyogenic Urticaria.—R. Campana reports the case of a patient suffering from urticaria, impetiginous eczema, and a pustule which led to furuncle, all at the same time. The same micrococci were found in all the lesions. There was a true urticaria, and not a mere papular septic dermatitis. In support of the view that this urticaria was of septic origin is the fact that here and there in the infiltrated matters were found blood corpuscles, some altered and some discolored, and distributed among the epithelial cells were lumps of pigment. This pigment was evidently of corpuscular origin, and was composed of granules, which were all alike and of a relatively small size.—*La Riforma Medica.*

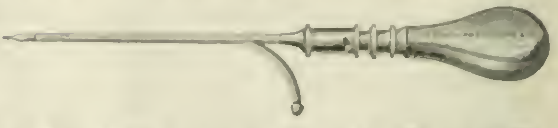
New Instruments.

AN IMPROVED TROCAR AND CANNULA

By JAMES R. HAYDEN, M.D.

NEW YORK

This above figure illustrates a very simple form of trocar and cannula, which being made entirely of metal, can be taken apart and sterilized by boiling. The tumor or cavity having been punctured in the usual manner, the trocar is withdrawn until it is stopped, at which time its point is just beyond the curved outflow tube, through which the fluid contents of the sac flow downward into a vessel instead of spurting backward as in the old straight instrument. The connecting bayonet joint between the trocar handle and the cannula is so packed as to prevent the backward passage of fluids and also the entrance of air. If so desired, a piece of rubber tubing can be attached to the curved outflow tube. My personal experience with the instrument has been in tapping hydrocele and aspirating the bladder, in both of which conditions it has given the greatest satisfaction. As it can be made of any desired size, it will, I think, be of practical value in tapping almost any tumor or cavity.



107 West Fifty-fifth Street.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 22, 1902.

	Cases.	Deaths.
Measles	989	35
Diphtheria and croup	300	54
Scarlet fever	299	25
Smallpox	55	13
Varicella	69	..
Tuberculosis	270	169
Typhoid fever	26	4
Cerebro-spinal meningitis	..	2

Surgical Treatment of Ascites.—N. Ito and K. Omi report five cases of ascites, which were operated upon after the Talma-Drummond method, which consists in suturing the omentum to the parietal peritoneum. The union thus formed favors the establishment of new blood-vessels, and thus prevents a large portion of the blood from entering the liver through the portal vein. The results which the authors obtained were very unsatisfactory, benefit being derived in only one out of the five cases, although all were operated upon very early in the disease before any considerable amount of ascitic fluid was present. In order to ascertain as nearly as possible the causes of their failure and the chief points of concern for the successful carrying out of the operation, they instituted experimental work upon dogs. Thirty of these were submitted to investigative operations. As the result of their study, they hold that the essential point for success is the obtaining of an extensive firm union between the intestines, liver, spleen, and parietal peritoneum. When such is secured, new brood vessels are developed in abundance, and those already existing are materially increased in size. Thus an extensive collateral circulation is set up, and a large portion of the blood is taken out of the portal veins before it reaches the liver. In order to obtain such a union it is recommended that the abdominal wound be not closed after the operation, but that it be abundantly packed with long strips of sterile gauze. These should be removed after twenty-four hours. The union by second intentions thus obtained favors the formation of granulation tissue and the extensive formation of new blood-vessels above alluded to. It is thought that by this variation the usefulness of the Talma-Drummond operation may be very much increased.—*Deutsche Zeitschrift für Chirurgie.*

Quinine Rash, with Report of a Case.—H. C. Wood, Jr., reports the case of a woman of thirty-five years who had taken two days previously, as a tonic, a prescription containing nux vomica and compound tincture of cinchona. Within a short time after taking the first dose she experienced stinging sensations along the forearm. A short time after this these areas became red. When seen, the eruption presented the appearance of a number of spots equally distributed over the extensor and flexor surfaces of the forearm, regular in outline, almost perfectly circular, from two to five centimeters in diameter, deep-red in the center, shading slightly toward the periphery, and surrounded by a slight macular rash. The temperature of the skin in the immediate neighborhood was distinctly elevated to the touch. There was, at first, according to the patient's description, some induration around the spots, but this had mostly disappeared when the patient was seen. Some of the spots had already faded and were copper-colored, in contrast to the bright red of those in active inflammation. There was slight itching. Temperature 99⅘°; pulse 88; no marked constitutional disturbances, no involvement of the mucous membranes. A placebo was ordered, and four days later the patient was seen again. The spots had faded to a marked degree, some of them actively desquamating.—*Therapeutic Gazette.*

The Treatment of Typhoid Fever, with Special Reference to the Use of Water.—G. W. Boot urges the free use of water by the mouth, by the bath, and by enema. Milk is the best diet, because, in addition to furnishing all the proximate principles necessary for the nourishment of the body in assimilable form, it furnishes more water than any other form of diet. But plenty of water should be given in addition. In his country practice, where tub baths are out of the question, the author has the patient placed on a rubber sheet, into which he sinks, forming a hollow. A pitcher of water at 80° or 90° F. is poured over him, and the water which accumulates around him is repeatedly soused over him by means of a large sponge, and cold water is constantly added. This reduces the temperature, stimulates respiration, and, by change of position, prevents hypostatic congestion of the lungs and pneumonia. Purgatives and enemata lessen the amount of infection; carry away the toxins formed in the intestines and eliminated by the bile; remove the toxins eliminated by the intestines; and lessen the local infection, by providing drainage for the infected Peyer's patches. They are not contraindicated, but rather indicated in diarrhœa.—*The St. Paul Medical Journal.*

The Salivary Secretion in Nervous Diseases.—A. Acquaderni reaches the following conclusions: Sialorrhœa is found in many nervous affections, and is a symptom to be classed with polyuria, glycosuria, and icterus. It is produced either by direct irritation of the salivary center (affection of the medulla), or by abolition of the cerebral moderating influence, or stimulation of the secretory tracks of the hemispheres (softening, hemorrhages), or reflexly through some lesion irritating the sensory nerves (neuritis—tic douleureux). In central paralysis of the facial nerve the salivary secretion of the affected side does not appear to be modified. and in no case is it diminished, but, if anything, increased. In peripheric facial paralysis there is diminution or abolition of the secretion, according to the severity of the lesion. Prognosis of sialorrhœa depends upon the affection in which it occurs; in some it indicates the progress of the disease, and in the absence of other bulbar symptoms, indicates involvement of the medulla (labio-glossal laryngeal paralysis, tâbes, anyotrophic lateral sclerosis). Persistent and prolonged sialorrhœa may, independently of the disease causing it, considerably aggravate the bad condition of the patient.—*Rivista Critica di Clinica Medica.*

A Case of Pseudo Cirrhosis of the Liver.—M. Strajesko reports the case of a man suffering from this rather rare disease, which is characterized by the symptoms of true cirrhosis, but differs from it anatomico-pathologically; there being no proliferation of the connective tissue of the liver. It is due to an inflammatory process, which is chronic in its course, and invades several serous cavities, resulting often in complete adhesions of the pericardium, the pleura, and thickening of the peritoneum covering the diaphragm and the liver. The cause of the inflammatory process is not known, but tuberculosis is frequently found in the family history of the patient. Clinical diagnosis of the disease is difficult, but is helped by coexisting heart disease and by long observation, which shows that the liver diminishes in size, that the spleen does not increase, and that ascites is quickly produced. Treatment consists in regulation of the heart's action and in puncture for the relief of the ascites. In some cases calomel is of use, and may even render the treatment by puncture unnecessary.—*Russki Arkhiv Patologii, etc.*

Agglutination in Typhoid Infection.—A. Di Donna has found that the serum of normal rabbits can agglutinate the typhoid bacillus in the proportion of 1:30. The serum of an immunized rabbit agglutinates the bacillus with which it has been infected, as well as other typhoid bacilli. The same serum may, in the proportion of 1:100, agglutinate bacterium coli which were cultivated on agar several months previously. With increase of the degree of immunity, however, there is decrease of the agglutinating power of the serum. The agglutinating power of a given serum is almost always in direct relation to the virulence of the bacillus with which the animal has been immunized. It is also greater when the intravenous method of infection is practised than when any other method is used. It is infinitely greater than the agglutinating power of the organic juices. A temperature of 60° C., acting for three hours on the serum of an immunized animal, does not destroy the agglutinating power. It is, however, lost in course of time, varying from twenty-five days to three months or more.—*Giornale Internazionale delle Scienze Mediche.*

Imperfect Osteogenesis.—Francis Harbitz thinks it doubtful whether true rachitis occurs during fetal life. He holds that the twenty cases, described by as many authors, were cases of imperfect osteogenesis. He describes a case of his own, that of an infant born six weeks before term, dying soon after birth, which was subjected to minute macro- and microscopic examination. The head was a mass of fractures, the clavicles, scapulæ and ribs were broken; there must have been over 100 fractures all over the body. Endochondral ossification was much delayed; periosteal ossification somewhat more advanced. The conditions shown by the miscroscope differed greatly from those found in rachitis syphilitic osteochondritis, and osteomalacia. The cause of the imperfect osteogenesis is obscure. In the case under discussion the umbilical cord was exceptionally short and very fragile, which might indicate insufficient nourishment as the cause.—*Norsk Magazin for Lægevidenskaben.*

The Treatment of Cold Abscess by Durante's Method.—Domenico Palieri reports two cases of extensive abscesses of the abdominal region treated by caustics, balsam of Peru, injections of iodoform, in glycerin, and injections of [illegible] and of [illegible] without good effect. Durante's method of injections of the emulsion of iodin and potassium iodide was tried, beginning with a dose every fourth day, and increasing to one every day. The suppuration gradually ceased and the fistulous passages closed, and after about thirty treatments the patient was perfectly cured. This treatment does not of course cure every case of abscess, but it has given excellent results. Mayer of Turin used these injections in twenty-five cases and came to the conclusion that they are well tolerated. He is careful to insert the needle subcutaneously, to avoid patches of necrosis. He thinks the treatment causes apyrexia and accelerates cicatrization. Cases which are not benefited by it are those with vast areas of suppuration, or those in which a large part is involved.—*Gazzetta Medica di Roma.*

Peculiar Case of Bladder Reflex.—Duncan P. Anderson reports the case of a man who suffered from attacks which occurred every two to six weeks and were characterized by polyuria and irregular heart action, the latter symptom outlasting the former by about twelve hours. Some of the attacks were so severe that the patient had to urinate and defecate at the same time. Examination gave no definite results except of an enlarged prostate, and, by a process of exclusion, the author came to the conclusion that the attacks of tachycardia and polyuria were secondary to some reflex from the bladder brought on by the enlarged prostate. Treatment consisted merely in the withdrawal of residual urine after micturition, and in washing with boric acid. After six months of treatment the interval between attacks was increased from about three to sixteen days to about a month, and the attacks were less severe in character.—*The Montreal Medical Journal.*

Acute Delirium and Uræmia.—A. Cullerre reports two cases which bear out the idea that some cases of delirium are due to nephritis. In the first case, that of a woman picked up in the street and taken to an asylum, suffering from delirium with hallucinations of vision and uncontrollable restlessness, an autopsy showed no other lesion than that of granular kidney. In the second, that of a man of forty-two years, there was mental excitement with confused religious mania, turning to mutism, and later to profound melancholy with suicidal notions. Amelioration of the condition occurred, but nine years later the patient again was seized with homicidal and suicidal mania, followed by prostration, aneuria, continual vomiting, mussitation, coma, and death. No autopsy was held, but the symptoms of uræmia were, in the three days preceding death, too evident to be mistaken.—*Archives de Neurologie.*

Iodic Purpura with Fever.—The patient in the case reported by A. Stengel was a man of twenty-three, who was taking the iodide of potassium for asthmatic attacks, the initial dose being five grains, gradually increased to eight grains, three times daily. Gradually iodic spots appeared, with a fever rising of 101°, but without apparent cause. The withdrawal of the iodide led to a subsidence of the fever and the gradual disappearance of the rash.—*Therapeutic Gazette.*

The Structure of the Crystalline Lens.—Th. Lominsky, by a method of injection and impregnation, has become convinced that the interstices between the crystalline fibers can be reached by colored fluids and by injected matters; and that the crystalline fibers are composed of a row of lanullæ which together form the characteristic hexagonal figure found on transverse section of the lens.—*Russki Arkhiv Patologii, etc.*

Regular Exercise.—Regular exercise is one of the best means of getting rid of superfluous flesh; but to do any good, it must be taken systematically every day, in the air, if possible, if impossible, then in the house, in the form of calisthenics. Do not knock yourself up by suddenly beginning to take tremendous walks, if you are not in the habit of walking, but do things gradually, beginning, say, with a couple of miles, or even less, a day, and taking longer distances as you get accustomed to the exercise. Perseverance in exercise pays as in most other things.—*Indian Medical Record.*

Jews in the United States.—It is said that the United States has now the third largest Hebrew population of any country in the world. One in every seventy is stated to be a Jew.

Population of Paris.—The population of Paris has increased 6.98 per cent. in the last five years. At the present time the total population is 2,714,068.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended February 21, 1902.

THE TREATMENT OF MALIGNANT GROWTHS BY THE *X*-RAY, WITH A PROVISIONAL REPORT ON CASES UNDER TREATMENT.*

BY WILLIAM J. MORTON, M.D.,
NEW YORK.

SOMETIMES, when one has progressed well along in a certain line of investigation, it is of value to "report progress." From this point of view I will present to-night a few thoughts upon the interrelation, in a curative sense, between malignant growths and the Röntgen radiation.

My simplest plan will be to report most briefly a few cases, with running comment upon their individual progress, and then to sum up, in general terms, the method of treatment and what is accomplished.

My greatest regret is not to have the pleasure of presenting to you the persons under treatment, but this is impossible, since they are all private cases, and would be unwilling to submit to our examination.

CASE I.—*Sarcoma at Elbow Joint.*—December 28, 1901: Miss E. P. was referred to me by her father, a physician. Preceded by some prior symptoms ascribed to rheumatism, this patient developed, in July, 1901, pain, inability to use the joint, and a swelling above the internal condyle of the left elbow. Pain and swelling increasing, sarcoma or tubercle was diagnosticated by Dr. Virgil P. Gibney, and the tumor excised. The wound not healing, in November, the arm was amputated at the upper third of the humerus by Dr. W. T. Bull. Microscopical examination showed round-celled sarcoma. Patient comes to me for treatment of the right elbow. This joint has developed exactly the symptoms experienced in the left before amputation, namely, pain and soreness on pressure, a steady ache and pain at the joint, inability to move it, and frequent twitching movements of the arm. I took a radiograph of the joint (exhibited), and found exactly the conditions shown by a radiograph of the amputated joint prior to operation, namely, a dark area (negative plate) of the external condyle, due evidently to a deficiency of lime salts of the bone at this point. The father, the patient, and myself were convinced that sarcoma had invaded the bone and its neighborhood.

Treatment by X-Ray.—December 30: No pain since first treatment. January 17: Treatments continued three times a week. Patient reports that elbow feels perfectly normal, and has resumed her normal use of the arm. February 6: Remains normal. February 20: The elbow for the last two weeks presents no symptoms of trouble whatever, and she uses it as usual. Took an *x*-ray picture to compare with prior *x*-ray picture of December 28 (exhibited). It will be observed that the dark area (on the negative) is much lighter, indicating, apparently, that the lime salts are again becoming normally deposited in the affected arc of the bone. So far as the evidence is at present attainable, this patient's elbow is cured, but with reservations.

CASE II.—*Extensive Carcinoma, Inoperable, Recurrent. Pain, Ulcerations, Fetid Discharge, Induration, nodular Enlargements, etc.*—December 11, 1902: In July, 1899, patient injured the left breast by a fall from a bicycle; had a sore spot in the lower part of the breast, and six weeks later on noticed a hard lump the size of a pea. In November this lump had become greatly enlarged. The entire breast and axillary glands were removed by Dr. Clement Cleveland. In February, 1900, she was again operated upon by Dr. G. Armstrong of Montreal, Canada, in an apparently most thorough manner. In about one year, January, 1901, two large lumps developed at the seat of the operation, and by September one of these had broken down into extensive suppurative ulceration. The entire left chest, even to the tip of the shoulder, has a tense burning sensation, is rigid with induration, violent red over a space as large as two hands; has some fetid discharge, steady pain, and pain darting into the back; her nights are sleepless; she cannot rest upon the left side. The disease has also invaded the entire right breast, and this is brawny, immovable, as if fast to the ribs, full of pain, it has a retractile nipple, other retractile areas, and various hard nodular projections.

Treatment.—The patient received five treatments in December, and went home for about four weeks for the holidays. She has since received seven treatments. The pain ceased from the moment of the first treatment. It returned slightly during the first weeks, but not at all since January 20. The fetid odor disappeared also at once. Of the two tumefactions, the open one began to discharge very freely, even to numerous small masses of débris, the size of a pea, while the other has diminished much in size. The tense and rigid skin of the chest and seat of the most active disease has become soft and pliable; the feelings of tension, burning and deadness have disappeared, numerous small nodules have softened and disappeared. The patient reports that so far as her feelings go she would not know that anything was the matter with her. The entire right breast also shows great changes. The retractile areas cannot be found, the angular nodules are rounded masses, the rigidity of the entire breast no longer exists. The hardening is becoming soft. The measurements are reduced one-half. The breast is easily movable.

We have here a case of most extensive carcinoma, in which no operation is possible, and in which the disease is speeding to a fatal termination. The effect of the *x*-ray, so far as I have gone, has been a remarkable amelioration of every symptom, a marked diminution in size of the new growths, and an entire cessation of pain and suffering.

CASE III.—*Carcinoma of Breast and of Region of Upper Third of Sternum.*—January 29, 1902: On September 11, 1899, at the Dewey parade, patient fell and hurt the right breast. A month later she discovered in it a small lump the size of a walnut; next she noticed retraction of the nipple, and found that the breast was considerably larger, then it became painful. Dr. J. Lee Morrill advised excision, also Dr. H. L. Purdy. This she refused, but was treated by an osteopath who reduced the size of the breast by manipulation. About two months ago discovered she had a "frightful pain" at the central upper portion of the chest, namely, in the region of the upper third of the sternum. This pain is of such a nature that she cannot stoop, it hurts her to extend the arms, to try to sing, or even to breathe. The sternal region gives her a sense of weight and oppression at the spot. Sharp pains radiate outward laterally on both sides, and shoot backward to the upper dorsal vertebral region and beneath the shoulder blades. Her sleep is much broken on account of pain and the necessity of rising to make applications for relief. Often the pain extends down the left arm like a neuralgia to the fingers.

---

*Read before the Harvard Medical Society of New York City, at its regular meeting, February 22, 1902.

Examination.—Right breast, a rigid, hard, tense, nodulated immovable mass, of a bluish surface color, nipple retracted, retractile areas above and below the nipple, several small detached nodules, measurement of hard mass between calipers, vertical five inches, horizontal, five inches. Has pain in the breast most of the time; it is a "dumb" ache, like a toothache. Has glandular enlargements in the right axilla.

"*Sternal Symptom.*" A flattish, but still distinctly elevated swelling or boss, three inches across in all directions, painful all the time as mentioned, and very painful to the slightest pressure; the elevation is about one-half an inch. January 31: Experienced relief from pain at once in the right breast after first treatment of day before yesterday. Breast softer, and she can button her dress over it without distress. Sternal region neither better nor worse. February 3: Reports that she should not know by her feelings that anything had ever been the matter with the right breast, it is softer, and appears to be dividing into lobes not before noticed. On the contrary, the sternal region gives trouble. It was relieved for twenty-four hours, then "started in again worse than ever"; it hurt to sing, to breathe, to lie down, or to move; compares pain to a severe neuralgia. The swelling is painful to the touch. At once, after treatment to-day, this swelling could be pressed upon without causing pain. The patient exclaimed, "All the pain is gone, and it is not imagination for it acts so every time." February 5: Right breast. No pain and smaller. Sternum—Relief from suffering for three hours after last treatment and then return of symptoms. February 7: Measurements of hard mass of right breast reduced from a vertical and horizontal diameter of 5x5 to 4x4 inches, retraction of nipple and all retractive areas no longer exist, several small kernels cannot now be found, nodular projections beneath the skin have flattened out, there is no pain. Sternal region—Great relief for twenty-four hours. February 9: Sternum—Swelling centralized and reduced one-half in its diameter, no longer painful to pressure, can take long breaths, and slept last night without pain. February 10: Similar report. February 14: Relief in sternum lasted 24 hours. To-day again pain and oppressive feeling.

A noticeable thing occurred during the treatment which was more than usually striking. At the end of three minutes, the patient said, "Why, there is relief now; it is like taking a hundredweight off; there is no doubt of it. I can breathe now; it is the first decent breath I have taken since yesterday." February 17: As mentioned, a severe treatment (five minutes to each side, one foot distance, brilliant x-ray as shown by fluoroscope) was given last time in my desire to favorably affect the sternal region. This morning the skin of the entire chest is very red, resembling a strong sunburn. Right breast, report "absolute peace and comfort" until this morning, when a slight pain returned. Measurement of mass three and one-half inches horizontally by two and one-half inches vertically, breast tending to flaccid. Mild treatment on account of the skin burn. February 19: The tumor of the right breast is now reduced from 5x5 inches originally to 3½x2½ inches. The sternal boss or flat tumor is reduced from three inches in diameter to about one and one-half inches, but varies in measurement, and tends to centralize to a more distant tumor. The patient has comparatively little pain, and often for one or two days at a time, none at all. February 20: Right breast, no pain and even flaccid. Sternum gives great pain yet, after the first twenty-four hours of relief is over. Treatment continued, erythema less. The patient was kindly examined for me to-day by Dr. W. B. Coley, and pronounced to be "typical carcinoma with advanced sternal involvement, absolutely inoperable." (Note.—March 1, no pain of any sort since record of February 20.)

Case IV.—*Carcinoma of Breast.*—February 11, 1902. Mrs. ——, referred to me by Dr. C. Francis Burley. Began five years ago with a tumor and pain in the breast. One year later, a part of the breast was removed by Dr. Augustin H. Goelet. Remained apparently well for eighteen months and then pain and a tumor returned in the original site. Has been having injections of echefolia administered by Dr. Whitney, and also taking this medicine by the mouth. Tumor of left breast three and one-half inches long by two and one-half inches broad. An excrescent red growth, size of large marble, at nipple and a discharging opening at lower portion. Tumor hard and nodulated. But little pain. Large lymphatic gland in axilla. February 18: At fourth treatment, red excrescent area quite pale and brownish; tumor softer and more movable and smaller. February 20: Measurements, three by two inches.

Case V.—*Cancerous Tumor of the Stomach.*—February 5, 1902: Diagnosis by Dr. Atwell of Hoboken. Symptoms, retching, vomiting, intense pain, located at epigastric region; inability to take food except liquid and hot. Sister died of similar disease. February 18. Six treatments; uniform report that the pain is entirely removed after each treatment, and remains away from six to forty-eight hours, can also take more food. It is noticeable in this as in all cases I have so far observed, that the pain is even annulled during the treatment, namely, in from three to ten minutes. February 20: Reports that she has had three successive days without "an idea of pain" whereas before treatment pain was constant daily.

Case VI.—*Sarcoma of Side of Head.*—January 25, 1902: Miss M——, a case of Dr. W. B. Coley's, referred to me for x-ray treatment. Began four years ago with a swelling in front of the ear, this cut out by Dr. Barnes of Kentucky; one year later, treated with caustic, soon swelling began anew with increased pain. Under treatment with Dr. Coley's serum the now large tumor decreased in size and became more comfortable. At present there is an extensive bony tumor in front of the ear and a soft tumor, about three by two inches, behind the ear, the soft tumor involving also nearly the entire tissue of the ear. The soft tumor has an "angry" appearance and presents a cluster of purplish red, hard, rounded divisions. The principal feature of both the hard and the soft tumefactions is the intense pain and sensitiveness to the touch, causing loss of sleep and necessitating also the use of ½ a grain of morphia every two to three hours. January 29: Third treatment. Reports that last night for the first time in ten months she had great relief and could sleep peacefully; she required no morphia at night and had reduced the entire morphia taken fully three-quarters in amount. January 30: Some return of pain. February 1: Very comfortable; less morphia; slept six hours. Complexion less "muddy." Tumors scarcely painful to the touch. February 4: Both swellings are reducing in size. Finds she can open her mouth to its full extent, whereas she has been previously able to get food into the mouth only with great difficulty, and even has had to force a small tablet of strychnia in between the teeth. A previously large gland in the neck is now scarcely to be found. February 7: All of the soft tumor and the ear can be freely handled without causing pain; the soft tumor is also softer and smaller. February 10: Has pain, but very infrequently and much diminished. Continues reduction of morphia one half. February 15: Soft tumor fully one-half reduced in size; looks dry, brown and, so to speak, "drying up." The principal shrinkage is of the upper four-fifths, which is now quite on a level of the unaffected skin surrounding it. February 19: Tumor in front of ear distinctly more conical, due to shrinkage around its base. February 20: Reports "splendid night, not a particle of pain." Morphia taken, when at all, not for pain but from long habit. Merely a small lump of the soft tumor remains.

It is to be noted here that the disease is not outside of the bone, but within, and that, therefore, results are not so rapid as they are when the malignant growth is superficial.

CASE VII.—*Epithelioma of the face.*—Patient referred to me by Dr. Clement Cleveland, December 13, 1901: Miss S., aged forty-four years. A small spot appeared on the left cheek in 1885; treated in 1886; cauterized in 1889; in 1890 broke down and was again cauterized; again cauterized in 1891, and this was repeated in 1893 and 1894. Galvanic electrolysis was used with some success in 1894. Since 1898 has been a large and deep open ulcer, varying in size.

Present Appearance.—Ulcer two inches in length by one and one-half inches wide. A large crater, one inch in diameter, extends with abrupt edges quite to the buccal mucous membrane and to the fibers of the orbicularis oris muscle, which look as if clearly dissected out. The ulcer presents everted and raised pearly edges, hard to the sense of touch. Its central portions are in a state of slough.

For an inch upward on the cheek, beyond the actual ulcer, is an extensive indurated area about ready to break down. Induration also extends outward from the edges from one-quarter to one-half an inch in all directions. The left side of the roof of the mouth is thickened, of uneven contour and indurated and evidently invaded by the disease.

January 15: Induration of the roof of the mouth has now entirely vanished; induration of cheek beneath the unbroken skin is softening and disappearing. Ulcer is reduced about one-quarter in size, and its edges are drawing together, as if cicatrizing — shows healthy granulations. The sloughing spot in the center was shielded by a piece of silver, cut to fit over and laid in over it. Treatments were continued three times weekly, under great difficulties of shielding certain spots and attacking others. February 5: Although doing very well, still to break down several indurated areas a severe treatment (vacuum tube equivalent to a seven-inch air gap, three inches distant, eight minutes duration) was given. February 8: Hard nodule at angle of mouth has softened. The entire ulcer, however, looks angry and venous colored, the granulations are dry and, as a mass, flattened out. February 14: As a result of the treatment of February 5, the ulcer has flattened out and reminds one of a dead jelly fish lying on the sand of a beach. February 17: Ulcer looks better and almost no induration can now anywhere be found. February 19: Same.

This patient kindly allows us to inspect the ulcer to-night. (Patient examined by members.) I present a photograph taken about four weeks after treatment began. Also some microphotographs of microscopic sections made by my friend, Dr. J. R. Taylor of Brooklyn. In his report to me he writes, "The microscopical examination of a nodule shows it to be a typical epithelioma." Although the ulcer itself in this case is not healed, it bids fair to most certainly do so; but its healing is delayed in its healthy parts and its healthy granulation tissue broken down repeatedly by the necessity of attacking the deep-seated portions of the disease, namely, the indurated areas beneath the surrounding skin not yet broken down. It is in these areas that the greatest gain has been made in this case.

CASE VIII.—*Carcinoma of Breast.*—January 30, 1902. Patient kindly referred to me by Dr. W. B. Coley. She presents a nodule, the size of a pigeon's egg, angular, and showing angularity where the skin lies over it; to palpation hard and apparently fixed on a rib; has some pain; formed at upper portion of the mammary gland. Dr. Coley had performed three removal operations for similar nodules, but the patient would not allow of more extensive operation. He had also used his serum with great advantage, but was desirous of observing the effect of the *x*-ray. This tumor may be distinctly seized between the finger and thumb and is about three-quarters of an inch in thickness. February 1: Second treatment. No sign of nodulation visible where formerly it pushed the skin outward. February 3: Marked diminution of size of nodule. February 6: One can scarcely find any swelling. February 10: Patient greatly exhausted by social duties and after four days without treatment, returns with swelling slightly appreciable to palpation. February 12: Diminution of size of nodule. February 13: Nodule difficult to find. February 19: Impossible to feel any tumor; none exists; cured, except as to the usual possibility of a recurrence.

It is satisfactory that the diagnosis, confirmed by the microscope, and the disappearance of this tumor can be corroborated by our distinguished presiding officer, Dr. Coley, present with us to-night.

The *x*-ray has undoubtedly rendered a fourth operation by the knife, and that, too, a very unsatisfactory one as regards ultimate recovery, unnecessary.

Other cases are under treatment, including an epithelioma of the throat, carcinomas of the breast and sarcomas, but their histories are too recent to be of especial value to report at this moment, except to state in general that in their cases relief from pain is immediate, and from twenty-four to forty-eight hours at least, in duration, that a reduction in size and hardness is soon apparent, and that the patients, conscious of relief and improvement in their condition, become happy and cheerful.

Observations upon the Above Cases.—Anæsthesia and analgesia, and mode of action.—The salient feature presented by a consideration of the above cases is the immediate and complete relief from pain. This in itself is no small contribution to the treatment of cancer. The *x*-ray, from this point of view alone, would seem to be preferable to the usual narcotic medicines. The action of the *x*-ray is frequickly as quick as the action of a hypodermic injection of morphine and as lasting.

In my opinion this analgesic action is due to the benumbing of the nerves of sensation. Equally and similarly the remaining nerve supply of the new growth must be benumbed. We have therefore a reduction in the force of the total innervation of the new growth.

May it not be that this reduction of innervation results in a reduction in the activity of the growth of the part and thus leads to a retrogression and cessation of its growth?

This view postulates an atrophy of the new growth due to lack of innervation. But my explanation of the total effect would extend even further than this paralysis of innervation, and would claim that the entire protoplasm of the part subjected to the radiation is to a greater or less extent benumbed in its activity. The result is a retardation of the protoplasmic activity of all the tissues, nerve as well as others. I would term the process a paresis or a paralysis of the protoplasmic activity. Exactly this effect I have produced with the *x*-ray upon small jelly fish as they moved about in the water of a salt-water aquarium. This paralyzing effect would affect the activity of a micro-organism, if such exist in cancer, as quickly (or perhaps more quickly) than the activity of the new-growth tissue. It would also, probably, affect new cells quicker than other ones.

Effect of the Situation of the New Growth.—When the new growth is superficial, or an open ulcer, a simpler problem is presented than when it is internal and covered with sound skin. In the former case the Röntgen radiation may be used with a power that may almost resemble the action of a caustic; in the latter case the operator is delayed by the danger of setting up a burn or a gangrene of the sound skin.

That superficial epitheliomata of considerable extent may be cured by the *x*-ray is now beyond question. Dr. Francis H. Williams of Boston, by his admirable work upon the therapeutic qualities of the *x*-ray, has convinced surgeons of this. He has reported three cases of superficial epithelioma thus cured. Dr. Wallace Johnson and Walter H. Merrill of Philadelphia have also cured several cases of epithelioma, reported as early as December, 1900.

That, also, broken-down, open, and ulcerating carcinomata, as in Dr. Gilman's case of Chicago, or surface sarcomata, as in Dr. Skinner's case of New Haven, and a recent case verbally reported from Brooklyn, N. Y., treated by Dr. Fiske (all undoubted cures), should be cured is more to be expected for the same reason, namely, that an open surface, or one over which no sound skin lies requiring to be guarded, may receive a severer treatment than skin-covered cases, or cases beneath a sound skin and within a bone.

But that carcinomatous new growths, not yet broken down and still covered by healthy skin, may be dissipated totally, as in Case VIII., and, almost entirely up to date of this report, Case III., is a newer fact and of extreme importance. For we are led to hope by such results that internal cancer, as well as external, may be cured. Corroborating the legitimacy of this expectation, is the fact that in the cases reported to-night the pain symptom of internal cancer is relieved just as in external cases, and proving that the *x*-ray actually reaches and affects the diseased parts.

In fact, one of the great advantages of the *x*-ray treatment is its far-reaching and general character; for instance, an entire chest may be cleared of disease, if present results are corroborated by further experience, where the knife, however skillfully used, could never search out every possibly affected lymphatic channel.

Method of Treatment.—I employ Ruhmkorff and high-frequency coils and static machines to actuate the vacuum tubes. The radiation from tubes actuated by any one of the three would seem to be identical.

I use the ordinary Jackson focus tube invented by Mr. Herbert Jackson of King's College, London.

Mr. Jackson placed the platinum anticathode at the angle now employed to direct the radiation out of a Crookes' tube, and deserves this credit, to the exclusion of all the minor names now attached to Crookes' tubes of the Jackson type. Every tube in use to-day for the production of the *x*-ray is a Crookes' tube as thus modified by Jackson, and would otherwise be comparatively useless.

Using an oscillatory coil, my average consumption of energy in treatment is three amperes at 110 volts, with a probable frequency of 100,000 to 200,000 oscillations per second. Using a Ruhmkorff coil, my average is three to seven amperes at seventy-five volts. Using a static machine, I use one having ten revolving plates, thirty-two inches in diameter, run at a rate of 300 to 400 revolutions per minute.

Screens may be of "tinfoil" or thin sheet lead. I pay no attention to grounding the screen, nor to insulating it from the patient, as so often strenuously advised. Granting that the electrostatic effects reach and affect the patient, this effect is harmless and a mere modicum of what is intentionally used in daily and beneficial treatments. I do not care to insulate or to ground, for I believe the "burning" is produced by the *x*-ray, and not by the electricity of the electrostatic field. Proof enough of this distinction is the experimental fact that no burning of a part exposed to the dark hemisphere of a tube occurs while at the same exposure burning has taken place in the light or radiating hemisphere. Were burning due to the electrostatic impulses the entire tube would produce it, since the entire tube sends forth these electrostatic impulses.

As to the quality of the radiation, namely, differences due to the degree of vacuum in the tube, undoubtedly great physical and therapeutic differences exist—probably much greater than we are now aware of. The low vacuum tube, actuated strongly and near to tissue, can exert a destructive influence in burning and production of gangrene which a high-vacuum tube under similar conditions will not. I prefer a high-vaccuum tube (vacuum equivalent to a seven-inch air gap), actuated not too strongly. The quality of the radiation from such a tube produces a blurred and "muddy" definition in the fluoroscope, or upon the photographic plate in contradistinction to the sharply-defined image of other conditions of the tube ("soft" and "medium soft"). The blurring is doubtless due to "diffusion" of the *x*-radiation after impact within tissue.

But as to the choice of a "soft," "medium soft," or high-vacuum tube, practice must differ according to the case to be treated. Superficial growths, with no intervening sound skin, may be treated by a soft or medium soft tube, while internal growths, covered by sound skin, are more safely treated with the high-vacuum tube. This is not to say, however, that a superficial growth may not be treated by a high-vacuum tube, and this, in fact, is the method I would at present advise.

It is necessary to emphasize here the great caution required to administer enough of the *x*-ray, without burning, or injuring to the extent of gangrene, the patient's tissue, and yet enough to cause retrogression of the new growth.

The treatment is a hazardous journey between Scylla and Charybdis.

Uncertainties and Dangers.—1. The absence of a definite measure of the "dosage." 2. The possibility of a "burn" or of gangrene. 3. The difficulty of ascertaining when the "danger point" of administration as regards burning and gangrene is reached.

Conclusions.—What is accomplished by the *x*-ray? 1. Relief from excruciating pain and constant suffering, often immediately. 2. Reduction in the size of the new growth. 3. Establishment of the process of repair. 4. Removal of the odor, if present. 5. Cessation of the discharge. 6. Softening and disappearance of lymphatic nodes. 7. Disappearance even of lymphatic enlargements not directly submitted to treatment and often quite distant. 8. Removal of the cachectic color and appearance of the skin. 9. Improvement in the general health. 10. Cure, up to date, of a certain number of malignant growths.

REGARDING THE INFECTIOUS AGENT OF YELLOW FEVER; A REPLY TO DR. SOUCHON.

By ALVAH H. DOTY, M.D.,
HEALTH OFFICER, PORT OF NEW YORK.

It can hardly be said that Dr. Souchon's communication, which appeared in the MEDICAL RECORD of December 28, has in any way damaged the argument already advanced that yellow fever is not transmitted by personal contagion, or by clothing, bedding, etc., nor has it proven that the mosquito is not the medium of infection in this disease. Dr. Souchon's remarks were inspired by a paper which I presented at the last meeting of the American Public Health Association* relating to the means of transmission of the infectious agent in yellow fever, and in support of the argument above referred to. In this paper I have introduced, not theories, as Dr. Souchon suggests, but evidence in the shape of reliaable statistics, which extend over a long period, and for which I have asked careful consideration.

Official reports of the different outbreaks of yellow fever occurring in New York City, extracts from which appear in my paper, indicate that during the period between 1798 and 1806, hundreds of cases of this disease were removed to Bellevue Hospital (then practically outside of the city), and to the Marine Hospital on Staten Island. These reports show that during this time but one case occurred among the physicians, their families, and the employees connected with these institutions, although there was free and constant exposure. The official account of this case, which only enhances the value of the statistics referred to, is as follows:

BELLEVUE HOSPITAL REPORT, 1798—JAMES HARDIE.

. . . . "In short, Dr. Douglas, one of the assistant physicians was the only person, residing there, who was seized with fever; but he had been in the habit of occasionally visiting his friends in the city, *and three days previous to his being taken ill had slept in a house the vicinity of which was highly infected, and it is more than probable that his sickness was occasioned by that cause.*" †

I have also referred to the report of Dr. Edward Miller, resident physician at Bellevue Hospital, who, in a letter addressed to Governor Lewis, under date of January 12, 1806, says: "No communication of the disease was ever observed in yellow fever hospitals situated at a distance from the city to which they belonged; no exception to this has ever occurred in any of the numerous seasons of the pestilence. In our hospitals, at Bellevue, the Marine Hospital on Staten Island, that of Philadelphia, or any other in the United States, provided the malignant air of the city has been avoided."

To the above I have added the statistics of the New York Quarantine Station, the records of which show that secondary cases of yellow fever have never occurred at Swinburne Island Hospital, to which place are removed all persons suffering with this disease who arrive at the port of New York. In addition, my own experience, which relates to the inspection and treatment of vessels and persons arriving at New York from yellow fever infected ports is given, and is in full accord with the result shown by the statistics above presented. In the official report of the transfer and treatment of cases at Bellevue Hospital and the Marine Hospital from 1798 to 1806 there is not the slightest reference to disinfection; moreover, we all know that during these early times the value and method of scientifically applying this important agent in the prevention of infectious disease was unknown. Therefore, in the consideration of the statistics presented by these hospitals, we are dealing with yellow fever where the freest exposure existed, and without disinfection. Moreover, the hospital reports referred to were made by physicians, who gave simply a statement of their experience, and were neither establishing or supporting a theory. I regard such data in the discussion before us as invaluable. Regarding this important array of evidence, Dr. Souchon is silent. He neither refers to, or discusses these statistics, nor offers an explanation for them which is in harmony with his theory. He states: "That yellow fever develops and spreads with difficulty in Northern climates, whereas the least spark which may pass through the North will set the South on fire." This is hardly in accord with the facts, inasmuch as we have indisputable evidence that at different times, between 1798 and 1822, yellow fever developed in New York City without difficulty, and with great virulence, and, so far as the rapidity of its propagation and its formidable mortality is concerned, it equalled that of outbreaks which from time to time have occurred in the South. Moreover, outbreaks of yellow fever about that period also occurred in Philadelphia and other Northern cities. Therefore climatic differences alone do not explain why yellow fever should propagate in the South and not in this section of the country. Futhermore, Dr. Walter Reed has shown, in connection with his experimental work in Havana, that infection does not follow the exposure of non-immunes to the clothing and bedding of those sick with yellow fever. Here is evidence to show that clothing, bedding, etc., is no more of an infective agent within than without the so-called yellow-fever belt. From other sections of the United States we have satisfactory proof that yellow fever is not contracted by personal contagion, or by contact with the clothing or other effects of those suffering with this disease. For instance, during the summer of 1855 a most formidable outbreak of yellow fever appeared in Norfolk, Va., after an absence of almost thirty years—excepting an occasional case brought to the city by an incoming vessel. Probably one of the most instructive and reliable accounts we have of this epidemic is found in a series of letters prepared for the Virginia Historical Society by Rev. George D. Armstrong of Norfolk,* whose valuable services during that trying period were well known. He was constantly with the sick and dying, and ultimately contracted the disease. The narrative of his experience is of great interest scientifically and otherwise. I submit a few extracts which have a direct bearing upon the subject under discussion. In concluding his history of the epidemic Dr. Armstrong says:

---

*Published in the MEDICAL RECORD, October 26, 1901.

† The italics are mine.—A. H. D.

*Published in 1856 by J. B. Lippincott & Co.

"Those who were active in ministering to the sick and who did not take the fever, did not take it as a general thing until, as an epidemic, it reached the part of the city in which they resided. *The cases of apparent exception to this general rule were, most if not all of them, I venture, like that of my nephew, Edmund Jones, who slept at night in a part of the town to which the disease had spread.** In my own case I was more than six weeks almost constantly during the day among the sick, the dying and the dead, often talking and praying with them when their breath was so offensive (for in this disease the breath generally becomes very offensive before death) that I have quitted the room sick at the stomach, and this in parts of the city where the fever was raging with the greatest violence, and yet I did not take the fever until, as an epidemic, it reached that part of the city in which I lived, and then I was one of the first to be prostrated by it. And I could mention many other similar cases to my own."

"Those employed in burying the dead, in so far as I know, did not take the fever until, as an epidemic, it reached the part of the city in which they dwelt. No man could have labored at his calling more faithfully than Mr. Dobbs, our principal grave digger. From early in the morning until late in the evening he was constantly at work in the cemeteries. I have myself seen him eating his meals there, and he labored thus before the order was issued forbidding interments in vaults. The stench from the dead bodies was sickening, and yet throughout almost the entire summer he remained as at other seasons. He lived at the extreme northern end of the city, the parts to which the fever extended latest of all, but it did extend to that part of the city, and then he and his wife both died of it."

"Those who resided in the adjoining county and came to the city during the day only, in no instance, that I have heard of, took the fever. Some in my own congregation there were who acted thus, and they all escaped. So with the country people who attended our markets, and there were some who attended throughout the season, not one of them that I have heard of died of the fever. Our citizens fled in almost every direction, many of them with the poison in their systems, and they sickened and died in almost every place to which they fled—in Philadelphia, Washington, in Richmond, in Petersburg, in Hampton, and on the eastern shores of Virginia. *Not less than thirty died in Baltimore, and twenty, at the least, in Richmond, and yet in not one of these places did a case of yellow fever originate by contagion from these sick and dying fugitives.*"*

Dr. Peter S. Townsend, who in 1823 published an account of the outbreak of yellow fever which appeared in New York City during the preceding year (1822), was firmly convinced that the disease was communicated by personal contagion or by the clothing and effects of the sick. However, when he analyzed the statistics which he had collected, he frankly admitted that the evidence in support of his theory was not entirely clear. Regarding this he says:

"It may be asked why the numerous cases of yellow fever in uninfected parts of the town, and who had either taken the disease in, or were removed sick with it from the infected district, together with the large quantities of furniture, bedding and goods brought out of this district, did not also communicate the disease. . . . Why, these, however, and the remaining thirty-nine scattered over other parts of the city, supposing some of them to have brought their bedding or clothing with them, did not communicate the disease to their physicians, nurses or attendants, or to the inhabitants living in the neighboring houses, it is perhaps impossible to say. I will not deny that several of these cases, from the confined situation of the apartment in which they lay and the inattention of their nurses, seemed to have been placed under circumstances particularly favorable to communicate the disease."

Here are presented reliable statistics which cover a period of a hundred years or more. These reports do not represent theories, but practical experience, the most valuable material that can be submitted in the investigation of this subject, and while it does not show that the mosquito is the only means of infection in yellow fever, it does furnish conclusive evidence that this disease is not transmitted by personal contagion or through the medium of clothing, bedding, etc. Such evidence cannot be set aside, and must be given most careful consideration in the scientific investigation of this subject. I invite Dr. Souchon to give us a frank expression of opinion regarding the statistics which I have presented.

The popularity of the belief that clothing acts as a medium of infection in yellow fever is due largely to the fact that heretofore we have had no definite knowledge regarding the manner in which the disease is propagated. The actual demonstration that yellow fever is transmitted by the mosquito goes far toward supplying the link which has been missing. In this way we are able to explain in a satisfactory manner why yellow fever occurs only in certain localities, why, under certain conditions, it may occur in New York, Philadelphia, and other places outside of what is known as the yellow-fever zone. The fact that mosquitos remain in close proximity to their home or breeding place will explain why yellow fever is frequently confined to certain localities in a town, and why secondary cases of the disease did not occur at the Bellevue and Marine hospitals, between 1798 and 1806, inasmuch as both of these institutions were far from the infected area. It also explains why we have not had secondary cases at Swinburne Island.

In connection with this part of the subject, it is of interest to note that during the prevalence of yellow fever in New York between 1798 and 1822 that the disease was confined only to certain sections of the city. Dr. Townsend, in giving an account of the outbreak in 1822, states that the disease first appeared at the foot of Rector Street, and afterward slowly crept to adjoining streets. The disease propagated in this manner in 1798. The outbreak first appeared at Peck Slip, a shipping district in the lower part of the city, and remained in the immediate neighborhood for a long time before spreading to adjoining sections. This is in full accord with the history of the epidemic which occurred in Norfolk in 1855, to which I have already referred.

As proof of the theory that yellow fever infection is transmitted by clothing, etc., Dr. Souchon cites twelve instances where this disease occurred among the crews of vessels after disinfection had been performed at the New Orleans and other quarantine stations. I confess that I am surprised that Dr. Souchon is willing to rest his case on this evidence, inasmuch as I can see nothing in it which can be accepted as satisfactory proof that yellow fever is transmitted by clothing, cargoes, etc., or which is inconsistent with the mosquito theory. Most of the vessels referred to by Dr. Souchon were from Vera Cruz or Havana. As Vera Cruz is less than eight hundred miles from the Mississippi State Quarantine Station, and as Havana is probably not six hundred miles from the same place, it is reasonable to assume that a tramp, or slow steamer, would take less than four days in its passage from either port to the above Quarantine Station; therefore a person having been infected in Vera Cruz or Havana could reach the said Quarantine and remain there a day or two before a period of incubation of five days had expired. Under these circumstances the fact that yellow fever was not recognized until after disinfection had been performed has really no scientific or practical significance. Furthermore, I believe that Dr. Souchon, as well as other distinguished and experienced sanitarians, have declared that in some cases yellow fever may occur after a longer period of incubation than five days. Therefore, why does not Dr. Souchon present this as a possible explanation of some of his reported cases, where the disease has developed after a period of five days from an infected port? For instance, in the case of the captain of the *R. D. Spear*, who had yellow fever eight days after leaving Key West (an infected port), particularly as he was the only one on the vessel who was allowed to land. To say the least, reliable evidence is wanting here to show that the captain contracted the disease through the medium of clothing. Besides, I believe we all agree that a person may be ill with yellow fever for a day or so before there is real evidence of it. This is particularly so among sailors, who reluctantly admit that they are sick. It is for this reason that, at the New York Quarantine Station, we have, for the past four years, taken the temperature of persons arriving from infected ports in addition to the regular inspection.

---

* The italics are mine.—A. H. D.

In regard to the bark *Excelsior*, reported by Dr. Souchon, we have the case of a sailing vessel departing from Rio Janeiro on May 10, and reaching the Mississippi State Quarantine on June 25, having been on the voyage forty-five days. Dr. Souchon reports that no sickness occurred on this vessel either at Rio Janeiro or en route to New Orleans. The *Excelsior* was disinfected at the Mississippi State Quarantine Station on June 26, and detained there for about twelve days, and then allowed to proceed with all well on board to New Orleans. Two days after arriving at the above place, or about fourteen days after disinfection, a member of the crew became sick with yellow fever. This was followed within a day or two by the appearance of three other cases of the same disease. The very brief report that Dr. Souchon makes of this and other cases to which he refers leaves us in the dark as to his explanation of them. Does he contend that these men were infected during the disinfection of the vessel, twelve or fourteen days previously? If so, does he not regard it as very strange that of the number of persons thus affected none developed the disease within the ordinary period of incubation—five days. If Dr. Souchon does not regard this as unusual, why can he not with just as much reason assume that the captain of the *Spear* contracted the disease in Key West? He was but eight days away from that place when he reported sick. Or does Dr. Souchon believe that the crew of the *Excelsior* contracted the disease after disinfection was performed? This would indicate that the treatment referred to was not effectively carried out. Those who are familiar with the thorough and scientific way in which Dr. C. P. Wilkinson, who was then Quarantine Officer (1880), performed his work will reluctantly accept this theory. A reference to Dr. Wilkinson's report of the *Excelsior* case, dated July 21, 1880, which appears in the report of the Louisiana State Board of Health, shows that the hold, cargo, cabin, and forecastle were disinfected; this was performed twice, and in order to do the work thoroughly, the cargo was shifted, this being possible, as there were but 3,600 bags of coffee in the ship, while the capacity of the hold was 12,000 bags. Besides, sulphur dioxide, carbolic acid, and copperas were used. A reasonable, acceptable, and practical theory would be that the men on the *Excelsior* contracted the disease on their arrival at New Orleans, inasmuch as they were there at least two days before any evidence of yellow fever appeared. In order to prove this is not a fact, Dr. Souchon must furnish conclusive evidence that yellow fever was not present in New Orleans at the time.

Sailors have but little clothing, and that, as a rule, is freely exposed. In the case of the *Excelsior* there had been no case of yellow fever on board, and the vessel was forty-five days in transit, through a zone said to be favorable to the development of yellow fever, yet no evidence of infection appeared during this time. Is this not reasonable evidence that the disease was not transmitted by the clothing of the crew?

I am not aware that Dr. Souchon, or any other health official, has presented statistics which tends to prove that disinfection has diminished the extent of outbreaks of yellow fever which from time to time have appeared in the South. On the other hand, I believe that it has been stated on excellent authority that disinfection has been of no practical value in this direction. Moreover, I am satisfied that we have reasonably conclusive evidence that yellow fever is not propagated by the clothing, bedding, etc.

Whether or not other means of propagating yellow fever exist, we know that the mosquito is a medium of infection. This knowledge furnishes us a means of protection against the extension of yellow fever, which hitherto was unknown to us, and which has proven to be most effective in preventing the extension of the disease. I refer to the construction of hospitals, properly equipped for the treatment of yellow fever, the use of netting, etc. In what better or quicker way can we bring about a solution of the problem before us than by assuming that the mosquito is the medium of infection, and acting accordingly. If there are other ways by which the disease is transmitted, they will, under this procedure, much sooner present themselves. I believe that the knowledge we now possess of this subject fully justifies us in taking this course, and I am quite sure the public would endorse it. I can see no other way by which this important matter can be settled and commerce relieved of unnecessary and unreasonable restrictions. To continue as we have been doing in following traditions and theories which are antagonistic to scientific investigation, and not advance far enough to meet on a common ground where this subject can be properly considered and acted upon, simply means that we shall make no headway. I sincerely hope that Dr. Souchon, whom we all know leaves nothing undone in his desire to protect the public health, will feel favorably disposed toward a movement which, I am satisfied, is dictated by modern sanitation.

A New Method for the Isolation of the Typhoid Bacillus.—M. Biffi describes the process, which consists in sowing the matter to be examined on broth, to which has been added serum possessing the property of agglutinating the bacterium coli, the whole contained in a test tube furnished with the Berkefeld filter. If the Eberth and the coli bacilli are both present, the latter as it develops will become agglutinated, while the former, being unaffected by the agglutinating serum, will manage to pass through the filter of porous earth, and can be collected in a state of purity.—*La Riforma Medica.*

PNEUMONIA IN THE LIGHT OF MODERN RESEARCH.

BY [illegible] A.M., YALE, M.D., [illegible]

[illegible]

Impressed by the prevalence of pneumonia and still further, by the tragedy it too often enacts in so many households everywhere, the following essay is undertaken by me with special reference to the cause of the fatality as well as the prevalence of the disease, and to the measures best adapted for its prevention.

During the year 1890 the average length of life in the United States was 31.1 years, and in 1900 this mean amount had risen to 35.2 years, which is a striking proof of the increasing welfare of our commonwealth. In the last decade there has been a decline of nearly 10 per cent. in the number of deaths in the domain of accurate observation, known statistically as the area of registration. Commercial prosperity invariably leads to improved sociological conditions and these, together with the notable advance in the science of medicine and sanitation, are the reasons for the lowered rate of mortality and the extended measure of human existence. But in spite of these facts, gratifying as they are, the ever-pressing question of unnecessary disease and premature death, with their consequent social and economical evils, remains open to the thoughtful layman and likewise physician, for serious consideration.

The death rate from pneumonia in 1890 throughout this area of registration was 186.9, and in 1900 it was 191.9 per 100,000 of the population, whereas in 1890 there were 245.4 and in 1900 there were 190.5 deaths from consumption under the same relative circumstances. Therefore while the last-named disease is upon the decline, pneumonia, as the chief destroyer of life in this country, is coming into fateful prominence. According to the statistics of the census year of 1900, the three most common causes of death were pneumonia, consumption, and heart disease, and in the order enumerated. Consequently, with such momentous facts as these before us, a discourse upon pneumonia, which may be styled the "King of Death," and its incidents cannot well be deemed unwarrantable.

Pneumonia is a systemic, self-limited disease, with localized pulmonary manifestations. It is almost universal in its distribution. Though it occurs at all seasons, the winter and early spring are its times of greatest prevalence. Both in frequency and in fatality it is in direct ratio to the density of population. With the exception of a few years in childhood, it pursues mankind, and with increasing deadliness, through all the decades, from infancy to old age. It is often the harbinger of death in alcoholism, certain chronic diseases, and in various conditions of debilitation. Of the aged it is the typical terminal malady. The negro race in this country is very prone to succumb to its ravages.

Pneumonia is undoubtedly an infectious disease and chiefly by means of the sputum, in the same manner as pulmonary tuberculosis.

The expectoration of pneumonia is not likely to be so widely scattered as that of consumption for obvious reasons, nevertheless, there is more danger of and in its dissemination than is generally appreciated. Numerous instances were recorded of consecutive attacks of pneumonia in families, in schools, in barracks, in penal and in charitable institutions, and finally it dawned upon the profession that these were something more than mere coincidences. Such observations were made long before the pneumococcus or micrococcus lanceolatus was isolated, cultivated, and proclaimed by Fraenkel and Weichselbaum in 1886 to be the "invariable cause of acute lobar pneumonia." The word "cause," by the way, in my opinion requires the qualifying word "exciting," in order that we may not lose sight of a very important element, namely, predisposition.

The birth of the germ theory in its causal relation to many of the diseases which are afflicting mankind, as a tentative conjecture, was hailed by me with enthusiasm; the subsequent growth of this wonderful hypothesis was likewise viewed with profoundest satisfaction. It has made clear and intelligible much that was formerly involved in obscurity and shrouded in mystery. It is one of the greatest achievements of medical science, and is destined to be the chief factor in the working out of the vital problem of unnecessary disease and premature death. Possessing a knowledge of the natural history of the contagious and infectious diseases, and a better understanding of what constitutes susceptibility, we can anticipate with confidence their gradual, but not less actual, extinction.

Although the discovery of an antitoxic serum, or of a specific drug of any description, has its sphere of usefulness, yet it is a comparatively narrow one contrasted with the universal and permanent benefit to the human race, that intelligent sanitation and organized preventive and restrictive measures must certainly accomplish. Preventive medicine is the remedy par excellence; drugs are, at best, but temporary expedients. We must chiefly devote our energies to the killing of the germs and to the checking of further germination. These infectious diseases are the direct results of a congregation of human beings and their ignorant or voluntary disobedience of the established rules of sanitation. We have but to behold the city of Havana at the present moment in order to see a reason for the belief that here finds expression. The eradication of pneumonia, the scourge of civilization, in view of the present limitations of our knowledge, seems well nigh impracticable. Still, on the other hand, a decided step has been taken in the right direction. It is now settled beyond question that the micrococcus lanceolatus is a uniform, unfailing agent, in contradistinction to diverse predisposing causes, of acute lobar pneumonia. Dr. J. J. Curry, in the *Journal of Experimental Medicine*, states that in 1896 he examined thirty-two consecutive cases of acute lobar pneumonia, and in every one the micrococcus lanceolatus was demonstrated. This microorganism is a somewhat elliptical, lance-shaped diplococcus that answers perfectly to Koch's law, which does not here require elaboration. The diplococcus pneumoniæ exists in the blood, heart, liver, spleen, kidneys, and other tissues of the body, as well as in the lungs. It is present, as a rule, in the diseases which complicate pneumonia, such as pleuritis, pericarditis, endocarditis, peritonitis, and meningitis. It is found almost invariably in the pneumonic sputum and, not infrequently, in the living blood. It occurs in all its malignancy in the mouth and bronchial secretions of many healthy individuals. It also dwells in a non-virulent condition in the mouth and throat of nearly everybody. The dust-laden atmosphere of the houses we inhabit and of the public halls we frequent is more or less permeated by these mephitic organisms. And the floating, powdered sweepings of our streets must necessarily contain a fair share of what is practically everywhere. Such a state of affairs would naturally suggest wonderment that mankind ere this had not been utterly exterminated. But, fortunately, it requires something more than the germ itself for the development of pneumonia. The importance of recognizing the ubiquity of these pneumococci and their genetic relation to lobar pneumonia rests primarily upon the manifest necessity of destroying these pneumococci during a seizure of the disease when expectorated. It is just possible, but not altogether probable, in the various instances where the affection is said to attack those in perfect health that the number of the microorganisms and their virulence are so overwhelming as to take by storm, as it were, the most robust individual. Contrariwise, there is much likelihood that this so-called perfect health is more apparent than real, and, if the truth were known, these persons have long been auto-infected and undermined by a chronic condition of suboxidation. In normal physiological conditions nearly all pathogenic germs are opposed, if not repulsed, by the inherent defensive powers of the healthy cells and tissues of the human organism. There was a picture in oil recently upon exhibition in the window of a well-known art dealer of this city, wherein is portrayed a small flock of sheep huddled together, and evidently lost in a snow-storm. Around these poor, cowering, half-benumbed creatures hover and soar a number of hungry vultures, eagerly awaiting an opportunity to attack their coveted prey, when resistance no longer shall be possible. This typifies the human tragedy now under consideration.

Among the conditions that tend to lower the resisting power of the body for the germs of pneumonia are the suboxidation already mentioned from an habitual lack of proper deep breathing, and the many hours daily spent in a polluted atmosphere. Few houses, schools, shops, factories, places of business, of worship, or of amusement, when filled with people, are adequately ventilated. The air of many of our public conveyances, such as the cars and ferries, when overcrowded, as they almost invariably are, is extremely poisonous. Going from the overheated, or the underheated, nearly always fetid, air of these places into the damp, chilly out-door air, in view of the known whereabouts of the pneumococci, is not infrequently a dangerous proceeding.

The average person seems to think that he can continue to neglect the ordinary laws of health, and somehow escape the logical consequence of this negligence. If in time of peace we should prepare for war, then equally, and for the same reason, in time of health we should prepare for disease. Nothing will so surely carry us through an illness, if it does not avert one, as a daily systematic attention to all that makes for healthfulness. Granting there is such a thing as undue solicitude in regard to matters of health and to the possibilities of infection, nevertheless, there is a vast difference between that and a calm, intelligent avoidance of the manifest dangers by which we are surrounded. The food we eat, the water we drink, and the air we breathe should all be matters of discrimination. In fact, the price of health, if not of life, is continual watchfulness.

The personal measures for the prevention of pneumonia, aside from the disinfection of the pneumonic expectoration, are the avoidance of undue exposure to inclement weather and of all crowded, ill-ventilated gatherings; reasonable attention to questions of sanitation; temperance in eating, in drinking—in fact, in everything; daily bathing, in order to insure a healthy action of the skin, and regular exercise in the open air, with special reference to complete respiration. There is nothing better constituted to purify the blood, and thus fortify the system against infection, than systematic deep breathing out of doors while briskly walking or engaged in horseback riding. Frequent changes of underclothing are exceedingly desirable. Linen network underwear is conducive to a marked freedom from acute nasopharyngeal and bronchial catarrhs. Active and unimpeded transpiration through the skin, complemental to the internal excretory organs, is a physiological necessity neither fully nor generally appreciated. Finally, viewed as a hot-bed of microorganisms, the mouth should be rinsed two or three times a day with a solution of formaldehyde in the strength of twenty drops, of the 40 per cent. solution, to a pint of distilled water; for it is salutary, if not absolutely prophylactic. These are some of the apparently simple, though actually important, expedients for self-preservation.

While pneumonia is to a great degree, if not entirely, a preventable disease, the practical difficulties involved in its prevention are evidently considerable. When the resisting power has been weakened by intemperance, by chronic disease, by neglect of hygienic and sanitary precautions, by old age, and by destitution, it is very prone to succumb to an encounter with the specific pneumonic microorganisms. Destitution, with its attending wretchedness, is largely a contributing factor in the prevalence of contagious and infectious diseases, and among them to the high death rate from pneumonia, especially in large centers of population, and any successful effort towards the alleviation of this condition is so much gained for the cause of preventive medicine, as well as philanthropy. The well-being of the poor insures the better being of the rich; the sanitary tenement lowers the death rate of the mansion.

The death rate for 1901 from all causes was: In Buffalo, 14; Chicago, 15.5; Philadelphia, 19; Boston, 20, and in New York, 20.5 per cent. No less than 10,482 persons died in this city last year from pneumonia. New York should be one of the foremost cities of the world in regard to sanitation, despite its size and the great drawback of her crowded, ignorant tenement population. Few cities are so advantageously situated as this for healthfulness, surrounded as it is by water, in almost perpetual sunshine, fanned in all directions by the winds, and in a climate that, for this latitude, cannot be called insalubrious. The methods to be urged upon the municipal authorities for the prevention of pneumonia are the enforcement of a more rigid observance in regard to the ventilation of schools, churches, theaters, shops, restaurants, and other such places of public gathering. The quality of our water supply, though it might be worse, could still be improved at the reservoirs by wholesale filtration. More than one city, both here and abroad, has settled this question beyond peradventure. In addition to the regular sweeping of the streets, they should be also flushed and thoroughly washed with water, weather permitting, periodically. Our extensive area of asphalt pavement would render this measure especially feasible and efficacious. When the streets have been carefully swept, and they are now being swept with care, thanks to the present Commissioner, and the sweepings carried away, there still, of necessity, remains a large amount of ungatherable residue, which is composed not of the dust of clean earth, but of germ-laden filth, commonly in a state of unstable equilibrium. If upon this pulverized remnant of these sweepings there chance to fall a gentle rain, the entire surface of the roadway becomes coated with a more or less thick layer of sticky nastiness, and only after a regular downpour are the highways in a temporary state of satisfactory cleanliness. In heavy showers like these nature gives the clue to what should be done regularly, and, if not from the hydrants, owing to the close proximity of our rivers, could be done at an outlay, effects being weighed, that would be comparatively insignificant. Is it not strange that, with all our boasted wealth, energy, enterprise, and intelligence, we should still be far behind some of the older cities of the world, such as

Paris, for example, in the matter of cleaning our thoroughfares. The defilement of our sidewalks by the filth of the city is a fruitful source of disease, as well as a crime against decency, and should no longer be tolerated by the authorities. Expectorating upon the sidewalks and indeed upon the streets at all should be prohibited by the Health Department. Here, again, we have something to learn from several cities of the continent. Much of this filthy, disease-spreading nuisance is due to thoughtlessness, a great deal to ignorance, and very little to a deliberate desire to offend good taste or to injure anybody. Already there has been a remarkable improvement thanks to the efforts of the members of the Health Board in respect to this vicious habit in the cars of the surface and the elevated railroads; hence it should not be considered Utopian, in view of these encouraging facts, to look with reasonable expectation for similar results from a like crusade in regard to our streets and sidewalks. It is my earnest hope that the honorable gentlemen now in charge of this metropolis will bear in mind the appalling death rate from pneumonia and employ their highest endeavors in furthering the movement toward better municipal sanitation.

Seeing that there is yet no specific remedy for consumption, the great reduction in its mortality during the last decade must be due to the exhaustive efforts of the profession in general, and the health officers in particular, to instruct the people in regard to its infectiousness, and the measures necessary for its prevention. The work of the surgeon is brilliant, its results immediate, and it is widely appreciated. Meanwhile the silent, persistent efforts of the physician in his laboratory and at the bedside, to devise means for the warding off, as well as the curing of, various diseases incident to his fellowman, do not so much appeal to the popular imagination. It is only after a considerable lapse of time, through the gathering of statistics, it becomes evident that certain maladies are disappearing, and that others are being greatly reduced in point of mortality. Cholera, typhus and yellow fever, for example, are practically things of the past in this country, and the death rate of pulmonary tuberculosis, as previously noted, has fallen off during the last decade 50.4 for each 100,000 of the population. Notwithstanding the general well-being of the inhabitants as a factor in this progress towards healthier conditions, to the medical profession pre-eminently belongs the credit for such priceless altruistic achievements. It is now further incumbent upon us, from humane and from scientific standpoints, to strive for these same results during the current decade with respect to pneumonia. There is no specific cure for this disease thus far, any more than there is for consumption. Wherefore, the course to be pursued with the one is the same as with the other in many particulars. Without exciting undue alarm, the people should be aroused to the danger of infection from pneumonia and told how it may be averted. Had these 10,482 persons died in this city within a week or a month instead of a year, of pneumonia or any other infectious complaint, drastic measures would have been taken without delay to purge the city of such a plague and pestilence.

In conclusion, let me epitomize what the foregoing thesis endeavors to maintain—that lobar pneumonia is universal in diffusion, in nature infectious, unequalled numerically, and in fatality unsurpassed. It is a malady that can be lessened in frequency and lowered in mortality, if it cannot be eradicated; at the same time this reduction in quantity and in destructiveness, for the most part, is to be effected by incessant sanitary promulgations.

DIABETIC COMA: SYMPTOMS, PATHOLOGY AND TREATMENT.*

BY ABRAHAM MAYER, M.D.,
NEW YORK.
ATTENDING PHYSICIAN TO LEBANON HOSPITAL.

This array of symptoms known as diabetic coma was first described as an entity by Kussmaul in 1874. These symptoms were noticed in diabetes by clinicians long before this time, but they were not recognized as being peculiar to the disease until attention was called to them by the noted internist. V. Dusch described it in 1854, and Griesinger in 1859 noted a complex of symptoms which we recognize to-day as characteristic of this condition without being aware that such were usually present in this state. He noticed that in one hundred cases of deaths in persons suffering from diabetes, similar symptoms showed themselves in eight cases. He described these as rapid loss of appetite, nausea and vomiting, burning thirst, severe epigastric pains and great weakness and restlessness, a temperature that varied between 36.7° and 39.8° C., and an intensely acid urine. These symptoms were followed by rapid death. Griesinger thought they were of uræmic character. It was Kussmaul who first drew attention to that peculiar respiration called air-hunger, so characteristic in diabetic coma, and which is known to-day as Kussmaul's respiration.

The premonitory symptoms which characterize the onset of diabetic coma may vary in individual cases. Amongst those which are invariably present before collapse and coma ensue are the excretion of a large and increasing amount of B-oxybutyric acid and diacetic acid forming the so-called acidosis, which will be referred to later on, and of acetone and ammonia. Very often these symptoms are noticed long before actual coma occurs.

As a rule, such symptoms as Kussmaul's respiration, severe epigastric pain, nausea, vomiting, etc., are the precursors of an attack of coma, yet this condition may set in without any warning whatever. Not infrequently the exciting cause may be some sudden shock, worry, undue muscular exertion, a long railway journey or some digestive error. Occasionally the attack comes on quite suddenly, and the patient is overcome with drowsiness and collapse. So that if the patient is seen in this condition for the first time, it may be impossible to differentiate the attack from apoplexy, uræmia, or cardiac paralysis. Often a sudden change of diet from a moderately rigid to a rigid proteid diet is the exciting cause. The reverse of this has also been noticed. The condition of the bowels, such as obstinate constipation, may favor the development of coma, very rarely a diarrhœa ushers in the attack.

Diabetic coma frequently follows such complications as tonsillitis, bronchitis, pneumonia, carbuncle, gangrene, influenza, and other infectious diseases; gastritis, renal or hepatic colic, various abscesses, anæsthesia and surgical intervention.

Many times a sudden severe headache is the earliest symptom noticed; dizziness is often present. At other times the patient may be nervous, excited or restless. Sometimes the restlessness is combined with unsteady gait, and he reels like a drunken man. Other times there may be great fear, jactation, and occasionally delirium or maniacal manifestations are met with. Not infrequently the symptoms first noticed are muscle tiredness or muscle pain, sometimes very pronounced in the lower extremities; or great lassitude may be the earliest symptom observed, with yawning or sighing, sleepfulness and increasing somnolence. There may be great aversion to solid food, and unquenchable thirst. The voice is changed; it has that husky quality reminding us of pulmonary phthisis, and speech is short, incoherent or mumbling. The breath has the peculiar chloroform odor of acetone, which is often so great as to permeate the entire room. The urine has the same odor. The skin is dry.

---

*Read before the Metropolitan Medical Society, December 17, 1901.

The respiration is at times irregular, but is usually of the variety described by Kussmaul as air-hunger. Very frequently this is the first symptom noticed at the onset of coma. Kussmaul's respiration is of a peculiar sighing character. The patient breathes with much exertion, using all the muscles of respiration, although the lungs and glottis are perfectly free. Inspiration is very deep and prolonged, expiration is short, and of a groaning or moaning character. Usually auscultation detects nothing more than increased vesicular murmur. The respirations are regular, only occasionally normal in number, and may increase to double the normal number as the condition progresses. In a very few of the quoted cases in literature, dyspnœa was entirely absent. In the numerous cases observed by the writer Kussmaul's respiration was present in the greater number.

Cyanosis may occur and is usually very slight, and limited to the nose, ears, hands, and feet. The temperature is often increased at first, then decreases rapidly as coma develops, and the skin becomes very pale and very cold.

The pulse is small and weak and increases in frequency, rising to 130 or more. The tension is low, blood pressure is diminished; the action of the heart is feeble but regular.

Albumin is usually present, though in small amount. A constant premonitory sign of coma is the appearance in the urine of a large number of short hyaline or granular casts, first described by Kültz in 1891. These casts sometimes occur in enormous number a few days before coma sets in. They are very constant, and I have always found them in the urine just before and during the attack. In those cases in which the symptoms of coma disappear, the so-called abortive cases, these casts disappear also, only to return on the reappearance of coma.

Convulsions rarely occur, and the knee-jerks are frequently absent. As a rule, the pupils react to light to the very last, though usually they are widely dilated. In more than half of my cases ptosis was marked. As the condition progresses and coma increases it is with the greatest difficulty that the patient can be aroused, and as the coma deepens, he lies perfectly quiet and listless, and in this condition passes away. Very rarely the patient may be aroused till the very last to take his medicine and nourishment. Excluding the abortive and aborted cases, coma usually ends fatally in from twenty-four to forty-eight hours.

Pathology.—Of the various hypotheses which have been advanced appertaining to diabetic coma, but two seem to be tenable:—

(*a*) That of acidosis or acid intoxication, first described by Stadelmann and verified by Minkowski, Kültz, Naunyn, and others.

(*b*) That of a specific toxæmia, as taught by Klemperer and von Noorden and their followers.

It has been observed that the urine in severe cases of diabetes contains sugar, even when all carbohydrates were excluded from the diet, and that such other products as acetone, diacetic acid, and frequently B-oxybutyric acid are also present in various proportions. At the same time, the excretion of ammonia, lime, and magnesia are increased, and it is also found that the alkalescence of the blood is diminished, sometimes very much so, a fact which never occurs in mild cases of diabetes.

Acidosis, a condition which includes the excretion of diacetic and B-oxybutyric acids, is the result of the disintegration or splitting up of fatty acids, and not of proteid substances, as was formerly believed.

No substance is so easily oxidized in the normal metabolism of the body as sugar. Physiologists tell us that in the combustion of sugar, other less oxidizable substances are also consumed. When for some reason the normal metabolism of the body is decreased the power of burning up the sugar of the body is also decreased; with lessened power of oxidation the sugar escapes in the urine, and with it such other secondary oxidizable substances which also escape combustion. Hence, B-oxybutyric acid, the mother substance of diacetic acid and acetone, is found in the urine.

Whether this acid exists in the body in severe diabetes, and circulates as such in the blood, as I believe, or whether this acid is the result of other butyric acids, such as the amidobutyric acid, is not important for us. Important is the fact that frequently a very large quantity of B-oxybutyric acid is excreted (M. Levy noticed in one case the excretion of 157 grams in twenty-four hours), and that this condition requires a very large quantity of alkalies for its neutralization. You know that the chief diet of diabetics are the proteids and fats. You must also remember that in the splitting up of the albumin molecule the phosphorus and sulphur form phosphoric acid and sulphuric acid, and that these acids also require alkalies to form salts for their excretion. Normally, the ammonia derived from the disintegration of proteids is combined with carbonic dioxide to form urea and water. But in these severe cases of diabetes the B-oxybutyric and other acids require this ammonia for their neutralization, and in this combination are excreted. When the system is so depreciated that not enough alkalies can be formed from the proteids, the soda and potassa bases having been seized upon from the beginning, these acids will unite with the lime and magnesia of the bone, and hence you have an increased excretion of ammonia, lime and magnesia. This whole condition is called acidosis, and while even a severe diabetic will endure this for a certain length of time—weeks or months, very rarely years—a point of tolerance will soon be reached, and then these various acids produce an acid intoxication and coma. This is the theory of the acid intoxication.

The toxic theory is really a continuation of the above theory. Klemperer supposes that these acids destroy protoplasm in a specific manner, producing a toxæmia. Such toxic substances, however, have never been isolated. Von Noorden goes a step farther and supposes that this circulating toxic substance paralyzes the central nervous system, and coma is thereby produced.

The rôle that Kültz's casts in the urine play in this condition is as follows: Kültz has shown, and it has been subsequently verified, that when the so-called "Kültz cylinders" appear in the urine before and during coma, a fatty degeneration of the epithelium of the uriniferous tubules takes place. Hence it seems not improbable that the kidney is unable to throw off the toxins which are the result of continued acid intoxication, they accumulate in the system, and coma results, a view also entertained by Domanski and Reimann in a late communication. It may be that the epithelium of certain portions of the convoluted tubules, including the ascending portion of Henle's loop, has a distinct function—that of excreting these toxins, just as they possess the property of excreting the solids of the urine, as Heidenhain has shown in his experiments with the indigo-sulphate of sodium. This supposition is strengthened by the fact that when a [illegible] or [illegible] Kelly's paste disappear and the kidney resumes its normal function.

It may be interesting to note here that experiments of injecting into the veins of animals β-oxybutyric acid to induce [illegible] diabetic coma have been made, though only with partial success. Dr. Herter of this city has recently tried this experiment on two dogs. The first dog died during the experiment, on account of imperfect technique. The second experiment was strikingly successful, the animal becoming suddenly comatose, it being impossible to arouse him by pricking the skin. For over two hours he lay in a stupor, and then regained his normal condition. It must not be forgotten that the β-oxybutyric acid is itself a toxic poison, also that the condition of acidosis exists and does [illegible] for a long time, so that the intravenous injection of β-oxybutyric acid ought to be continued for a long time indeed to approach anywhere near the pathological condition of severe diabetes.

There is still another point to remember. A hyperglycæmia exists in diabetes mellitus. What influence bacteria may have in such a circulating medium, especially when the alkalescence of the blood is much decreased, one can only conjecture. Certainly this point should be further investigated. It may throw some light on the pathology of the subject.

Treatment. Severe cases of diabetes mellitus which show a marked reaction to Legal's and the ferric chloride test with increased ammonia and B-oxybutyric acid secretion are always on the danger line of coma, and our efforts should be directed towards warding off this complication as long as possible by reducing, if possible, the acidosis and ammonia excretion. The enforced method of dieting in diabetes has much to do with this acidosis. The prime object in all cases of diabetes mellitus is to reduce the sugar secretion, and by so doing to reduce the hyperglycæmia. Hence all carbohydrates are excluded from the diet which now consists of proteids and fats, and from these two divisions of food a requisite number of calories are made up to keep the body in nutritive condition. But it has been shown that at a certain stage in diabetes, which is really the critical period of the severe form, the fats increase the excretion of acetone and diacetic acid, which, as you have seen before, are the results of the acidosis. Hence the danger of a fat diet. At the same time few patients can stand such a dietetic régime for any great length of time without gastric disturbances resulting. The proteids, too, favor by their disintegration the production of toxins, and many authors believe that the toxæmia of the latter stage of diabetes mellitus is produced solely by the disintegration of the ingested albumins. So that a rigid diet of proteids and fats should not be continued. It has been found that by giving carbohydrates in this condition the acetone and diacetic acid excretion are lessened and that digestion is improved; the sugar excretion, however, is then usually increased, and a condition of inanition eventually occurs. The carbohydrates which such patients must receive in their food may consist of moderate quantities of farinaceous broths, bread, potatoes and levulose. The best results are obtained from milk, and about one quart may be allowed in twenty-four hours. Experience has taught me that lactose is better borne in severe cases than any other form of carbohydrate.

The condition of the whole digestive apparatus must command the closest attention, and no article of food or admixture of foods given which may cause dyspeptic disturbances. Especially in acidosis, no [illegible] conditions favor the development of coma as much as [illegible]. Constipation must be overcome by either massage, enema, or such laxatives as aloes, rhubarb, or calomel, alone or in combination. Protect the patient from mental and intellectual exertion, excitement and irritating influences. Acids and narcotics must not be given. For the avoidance of impending coma all authorities recognize that the most important point is the reduction of the acidosis, and increased ammonia excretion, and advise the administration of very large quantities of alkalies, especially the bicarbonate of soda, by mouth, rectum, intravenous injection, or by hypodermoclysis. Enormous quantities, according to Lépine, Naunyn and others, must be injected at the same time giving as much by the other channels as the patient will stand.

The normal excretion of ammonia in urine is less than 1 gram in twenty-four hours, and forms 5 per cent. of the total nitrogen excretion. Diet influences this excretion markedly. On a vegetable diet a healthy man excretes .4 gram; on a mixed diet .6 gram; on a proteid diet .875 gram daily. Because of their meat-fat diet diabetics excrete somewhat more than this quantity, and about 1 gram is taken as the average for such patients. But in severe cases much larger quantities are noticed, depending not only upon the diet, but also on the fatty and other acids present in the system. Such large quantities as 5-12 grams *pro die* have been observed. Stadelmann, who has especially studied this subject, says that diabetics who excrete 2, 4, 6 or more grams of ammonia daily require constant watching and are always in danger of passing into coma, and that diabetics who have the disease in a severe form, and who show an increased excretion of ammonia in their urine are only to be put on a rigid diet with the utmost caution, and always with the simultaneous administration of alkalies.

The action of alkalies on the excretion of ammonia in urine, according to Camerer, shows that when these are given even in moderate quantities, the amount of ammonia and phosphoric acid in acid salts is much diminished. Camerer experimented on nine healthy subjects for seven successive days, giving on the second and third days 8 grams of bicarbonate of soda with 7.5 grams of citric acid, and on the other days giving no soda at all. The results are shown in the following table:

Day of Experiment	Average Excretion in Grams of N in Twenty-four Hours of a Healthy Individual.				
	Total Nitrogen	Urea N.	Ammon. N.	Total P_2O_5	P_2O_5 in Acid Salts.
1st day no soda given	11.1	9.7	0.55	2.4	1.4
2nd " soda "	11.5	10.0	0.35	2.3	0.8
3rd " " "	11.2	10.1	0.25	2.3	0.4
4th " no soda "	11.9	10.3	0.29	2.5	0.9
5th " " "	10.0	8.8	0.43	2.3	1.3
6th " " "	12.0	10.8	0.53	2.6	1.5
7th " " "	14.7	12.4	0.75	2.8	1.8

Thus it is shown that on the days when no soda was given the ammonia excretion rapidly increased, and when given a very decided diminution was observed.

In diabetes the alkalies do not influence the excretion of ammonia as much as in the healthy subject, and hence larger quantities must be given to bring about the desired result. Therefore, in the prodromal stage of coma, and even before this time, it is wise to give the patient as much soda or other alkalies as he can take, the physician being influenced by the reaction of the urine, and the condition of the digestive system.

In the year 1900, Leo Schwarz, before the Congress für Innere Medicin in Berlin, read a paper wherein he showed that the higher oxidation products of glucose and glycuronic acid, called respectively glyconic and sugar acids, when given in large quantity, produce a very decided diminution in the excretion of acetone and diacetic acid. Schwarz was led to make these experiments from the fact that all carbohydrates have this effect. It was but natural, then, that he should try the effect of these drugs in the coma of diabetes, and in the *Prager medizinische Wochenschrift* of this year he relates a case of coma of which the following are the essential points: Patient, very young man, weighing forty-five kilos, entered hospital November 12, 1900. First severe attack of coma, November 19, was successfully treated by 70 grams of glyconic acid, neutralized by bicarbonate of soda. Patient was up the following day and remained well for three weeks. December 10, second attack of coma, also successfully treated by 50 grams of glyconic acid, neutralized by bicarbonate of soda. Patient remained well for fifteen days, and was up and about. On December 26 patient had a third lethal attack of coma. The supply of glyconic acid had been exhausted, and although every effort was made to restore the patient, he succumbed. This medication certainly heralded a great advance in the treatment of this terrible condition, for it seems that something rational had been found to reduce the acidosis and abort coma when it occurs.

Another rational mode of treatment would be the introduction into the system of a sufficient quantity of ammonia to unite with the various acids found in the condition of acidosis, so that by their neutralization the acid intoxication would be reduced, the alkalinity of the blood kept at its normal, and the disintegration of proteids prevented. Acting upon this proposition, I believe I have accomplished the same results as Schwarz in averting coma by the administration of very large doses of the drug called urotropin, formin, or aminoform, as a brief history of the following case will show:

W. P., thirty-seven years old; no specific history; disease discovered in 1897; has been abroad several times; in various health resorts, the last time in May and June, 1901; maximum weight at that time one hundred and three pounds. First seen by me August 23, 1901; weight, ninety-three pounds, so that he lost about ten pounds in two months. Sugar 5 per cent., marked acetone and diacetic acid and large amount of B-oxybutyric acid present. Ammonia increased. Quantity of urine voided eight pints. Albumin present; no casts. On August 27 he weighed ninety-six and one-half pounds, so that in this short time he increased three and one-third pounds in weight. On August 30, although in a very weakened condition, he left the city to join his family in the mountains, and when he returned, on September 11, he weighed but ninety pounds, and his condition was very miserable. The acetone in the breath was so marked that it pervaded the room and was recognized by others. He could barely walk. On September 23 patient showed symptoms of developing coma, Kussmaul respiration, severe epigastric pain, increased pulse, sensorium blunted. Kültz's casts present in large number, slightly elevated temperature; dilated pupils, great somnolence, some cyanosis, very marked acetone breath. Patient was at once given twenty grains of urotropin, repeated again in a half hour. The bowels were thoroughly evacuated, hot compresses applied to the chest, and an ounce of whiskey given by mouth. Toward noon respiration became normal. Urotropin again given in the same dose; pain disappearing; ptosis, which was present before, has disappeared. Sensorium clearing. In the evening the patient was again in his previous condition, the next day was out of bed and able to go about some. The next following day no cylinders could be found in the urine. Of course during all this time and long before this time, I had given the patient large quantities of carbohydrates in hopes of affecting the acetone excretion. And during all this time he was given as much bicarbonate of soda as he could take—from one to seven drachms daily, usually—in imported Selters water. Patient's condition remained stationary for some time; it even improved a little bit, so that on October 12 he was able to see me in my office. At that time he weighed eighty-six pounds. Until this time the urotropin had been continued on and off in decreasing doses. He seldom got less than twenty or more than sixty grains daily, but about this time it had to be discontinued on account of the frequent diuresis, which the drug produced, and which interfered with the patient's rest at night. On November 10 symptoms of impending coma were again present, which were again successfully averted by urotropin. On two subsequent occasions coma was also successfully combated. The most distressing symptom was the fearful loss of appetite from which the patient suffered, causing a continued loss of weight and strength. I had literally to force his food and drink, and the amount taken daily was rarely more than the equivalent of six or seven hundred calories. In this way things progressed until the morning of December 6th. After resting very well the previous night, the patient awoke with a very pronounced Kussmaul respiration, and I saw him very shortly after. Within the next few hours the patient received seventy grains of urotropin, although swallowing was extremely difficult, apparently from the great weakness only. As in the previous paroxysms the reduction of sugar in the urine just before the attack was very marked—from 5 per cent. to 1½ per cent.—while the acetone in the breath was apparently much increased. Kültz's casts were again present, though much less urine was voided on account of the inability of the patient to take much drink. Coma was successfully averted, and although the patient expired about twenty hours after the beginning of the last, fifth attack, he retained his consciousness and spoke to the very last. His exitus was the result of the asthenia.

My reason for using urotropin in this connection is that it is a chemical combination of ammonia and formaldehyde, which in the presence of an acid splits up in the body into its component parts. The splitting up of this drug takes place in the kidney, the ammonia being rapidly absorbed by the kidney veins, thereby entering the circulation and neutralizing any acids that may be present, while the formaldehyde passes out with the urine.

I have only given you the results of a single case in which I have used this drug for the avoidance of impending coma. The results of one case are not sufficient to make any specific claim, and farther use in more cases will be necessary in order to prove the efficacy of this reasoning.

The Dangers of Wearing Flannelette.—Presumably on account of the alarming number of recent deaths of children in Liverpool, owing to the ignition of flannelette garments, the Watch Committee have received a communication from the Home Office calling attention to the frequent fatal burning cases which took place in that city through the ignition of young children's clothing.—*Lancet.*

A NEW TEST FOR ALBUMIN.

BY [illegible] PH.D.,

[illegible]

This new and simple test is based upon the following facts: (1) Albumin is coagulated by carbolic acid; (2) equal volumes of non-albuminous urine and a mixture composed of equal parts of carbolic acid and glycerin form an emulsion which clears up entirely upon agitation, leaving a perfectly transparent and slightly refractive liquid; (3) equal volumes of albuminous urine and the above mentioned carbol-glycerin solution when mixed together produce a white turbidity which remains in spite of agitation and does not precipitate on standing nor redissolve.

The test is very sensitive, distinctly showing the presence of 0.1 per cent of albumin in the urine, the degree of turbidity being proportionate to the percentage of albumin contained in the urine.

Numerous and repeated experiments were made by me to substantiate the observation that this turbidity occurs only when albumin is present, and, furthermore, that it is due to the presence of albumin and is a suspension of coagulated albumin.

For this purpose many specimens of both nephritic urine and urine of patients suffering with cystitis have been tested, as well as numerous specimens of urine proved free from albumin by the recognized and generally used reagents for the detection of albumin.

In no instance did a urine, shown to be free from albumin by the recognized tests, present the slightest turbidity by this new reagent, nor did a urine, proven to be albuminous by the same tests, fail to show the characteristic white turbidity after treatment with the carbol-glycerin solution.

The method of applying the test is very simple, and requires as little or less time than the other reliable tests for albumin, and, as the carbol-glycerin solution is a non-irritating mixture, it is much to be preferred to the disagreeable nitric acid.

The solution consists of carbolic acid and glycerin, equal parts. Glycerin is added to prevent the formation of a permanent emulsion between the carbolic acid and the watery element of the urine, and is added in excess so that no possible error can occur from this cause.

Test.—2 c.c. of carbol-glycerin solution are poured into a small test tube, and 2 c.c. of the filtered urine are added. Mix thoroughly with a glass rod, or agitate. If a clear, transparent liquid results, there is no albumin present; but if the slightest turbidity is noticeable, the urine is albuminous.

[illegible] PARK PLACE.

Bone Filling with Amalgam.—J. H. Barbat reports the case of a man with an ulcer of the leg contracted in the tropics, and which led through a fistula to the diseased tibia. The diseased portion of the bone was exposed and removed, and the cavity was filled with ordinary copper amalgam until the whole surface was covered, leaving a hole which was partly filled with dental cement, the top being covered with more amalgam. The skin was sewed over the filling and dressings were applied. The wound healed except at the upper angle, with relief to all symptoms. The small opening at the upper angle refused to close, and probing revealed the fact that some of the bone had broken down. The amalgam was removed and the bone was found in good condition, except at the upper end, which was curetted and the cavity filled with formalin gelatin. This was in turn removed, leaving a large cavity covered with a healthy surface. In time the skin grew down into the cavity, and complete healing finally ensued.—*Occidental Medical Times.*

Clinical Department.

A SEVERE CASE OF DIPHTHERIA INVOLVING THE PHARYNX, LARYNX, TRACHEA, BRONCHI AND PROBABLY THE ŒSOPHAGUS AND STOMACH.

BY J. [illegible] MAC[illegible], M.D.,

NEW YORK.

[illegible] IN THE NEW YORK [illegible]

The following rather severe case of diphtheria is, I think, of interest enough to be reported.

J. M. consulted me on November 5, 1901, about his son Herbert, who had been croupy since the morning of November 3, and for several days before that had not appeared well. The child was a thin, pale, and anæmic boy, eight years of age; he had never been strong. He was a mouth breather, had suffered from frequent attacks of tonsillitis, and had had both measles and chickenpox some years before. I found the child sitting up, restless, and with a very anxious expression; he had a croupy cough and was so hoarse when he tried to speak that he could scarcely be understood. His pulse was rapid and rather weak, oxygenation was poor, and the cervical lymphatics were considerably enlarged. Upon examination of the pharynx, both tonsils were found enlarged, the right was much inflamed, and on it was a large patch of dirty grey pseudomembrane extending to the posterior wall of the pharynx.

The child was so nervous that it was impossible to obtain a view of the larynx. Of course, there was no time to wait for the report from a culture, and the boy was at once given an injection of 3,000 units of antitoxin. Steam inhalations and other remedial measures were ordered, and I promised to call again in a few hours.

As I left the house of another patient a few doors away, some fifteen or twenty minutes later, the child's father called to me in a very excited manner saying his boy was suffocating. I found the patient suffering intensely. His face had a dusky hue, he was more restless than before and was quite cyanotic, in fact, his lips and finger nails were blue. His arms were stretched over his head, and with each attempt at inspiration, the supra- and infra-clavicular and upper abdominal regions were deeply depressed, and he gave every symptom of impending suffocation.

His condition was so grave that it demanded immediate relief. As my recent experiences with intubation in advanced cases had been rather discouraging, it was decided to do a tracheotomy at once. With the efficient aid of Dr. John Erhard of this place, the child was etherized, the trachea was promptly opened, and a hard-rubber tracheotomy tube was inserted. The patient rallied nicely, the cyanosis cleared up at once, and he was wonderfully relieved.

Calomel fumigations were ordered and the steam inhalations continued. The child coughed considerably and had rather a restless night.

November 6, the patient was in fair condition; pulse 130, temperature 101.8°, oxygenation good. The stomach was irritable, and all food was vomited. He had a fairly comfortable day, and in the evening vomited a large piece of membrane. The patch in the pharynx remained unchanged.

November 7, the boy had a comfortable night; pulse 128, temperature 99.8°. The tracheal wound looked well. At 1.30 P.M., the child had an attack of dyspnœa, and as I was out of town, Dr. Erhard was sent for. He cleansed the tube which was obstructed, and the child breathed easier. Three hours later he had a more severe attack of dyspnœa. I removed the entire tube and cleansed the wound carefully, but without relief. A soft catheter was then passed down through the trachea to the bifurcation. Violent cough was excited, and several good-sized pieces of membrane were expelled, with such force that they flew across the room. A silver tube of larger caliber than the rubber one was inserted, and the child was greatly relieved. The pulse was feeble and at times intermittent, and strychnine was given hypodermically. The child was still nauseated, and made signs that he had great pain on swallowing. As he absolutely refused nourishment most of the time, nutrient enemata were ordered.

November 8, the patient had a restless night; the pulse was weak and he appeared exhausted. He still refused nourishment and vomited several large pieces of membrane. I was called four times this day to relieve severe attacks of dyspnœa, in two of which death seemed imminent. The trachea became obstructed, and passing a catheter into it was difficult and afforded no relief. So I decided to curette the trachea as reported by Scudder and others.

The tube was removed and the child was held in an inverted position by the nurse. A small flexible curette was passed through the tracheal wound down to the bifurcation, and the whole surface was rapidly curetted. There was but little bleeding and considerable relief followed. Later the patient became greatly distressed and ogygenation was poor, although the trachea was quite clear.

Loud bronchial râles could be heard over both sides of the chest. The child's condition was getting desperate, and it was decided to risk dropping some artificial digestant into the trachea. This was done, a few drops of a digestant solution being instilled into the trachea every hour. When I left the child at 1 A.M., he had Cheyne-Stokes' respiration and an intermittent pulse, and I thought his chances of recovery were very poor.

November 9, the patient had a restless night, and coughed up a great deal of membrane. The stomach was still irritable. He was very weak, but oxygenation was better and breathing much easier.

November 10, he had a fairly good night, though still coughing up quantities of membrane. He vomited nourishment and large pieces of membrane, also considerable of the latter passed per rectum. I attempted to remove the tracheotomy tube, but the child was so distressed that I was obliged to reinsert it.

November 11, improving. The tracheotomy tube was removed. The boy had passed only eight ounces of highly albuminous urine in twenty-four hours.

November 12, much improved. Has passed almost a normal quantity of urine. Several large pieces of membrane found in stool. From this time on improvement was steady, but more or less membrane was found in every stool, and on November 18, a piece six inches long and an inch wide was passed. Nourishment had to be almost forced into the child until November 19, when he began to take it more willingly, and on this day membrane was found in the stool for the last time.

The chief interest in the case lies in the extensive surface covered by the pseudomembrane, which I believe passed as far down as the smaller bronchial tubes. From the dysphagia, anorexia, nausea, vomiting, and finally the large quantities of membrane found in the vomited matter and stools, I think there is no doubt that the œsophagus and stomach were also involved by the diphtheritic process.

This patient received 13,000 units of antitoxin during his illness, and the calomel fumigations were used every one or two hours, three ounces being used in all.

How much the instillation of the digestant into the trachea had to do with the child's recovery may be questioned, but certainly there was marked change in his condition for the better within fifteen hours after it began to be used. As a strict quarantine could not be maintained on account of lack of space, the other six children in the family were given immunizing doses of antitoxin. None of them contracted the disease, excepting the youngest, a child eighteen months of age, who developed marked laryngeal stenosis and a rise of temperature, but everything cleared up nicely in twenty-four hours, after an injection of 2,000 units of antitoxin.

HYPERTROPHIC AND ATROPHIC CIRRHOSIS OF THE LIVER.

By JOHN A MITCHELL, M.D.,
NEWARK, OHIO.
SURGEON TO THE NEWARK CITY HOSPITAL.

From the fact that there has been of late doubt expressed by some medical writers as to whether hypertrophic and atrophic cirrhosis of the liver were not two distinct diseases bearing no relation to each other, rather than, as is generally understood, being simply different stages of the same disease, I beg to report the following case:

Mr. J., aged thirty-five years, father of two healthy children, consulted me in August, 1899, for a trouble, the symptoms of which indicated some affection of the gall-bladder. There was almost a constant feeling of pain or uneasiness in this region, the pain at times becoming very severe. The gall-bladder was distended and tender on pressure. The edge of the liver could be easily felt below the border of the ribs. After a month's treatment, which probably had nothing to do with what followed, he passed a number of small gallstones, the largest of which were about the size of a grain of corn. Some relief followed the passage of these stones, but in a short time the pain returned. Suspecting the presence of a larger stone, too large to pass through the ducts, I sent him to the hospital for operation. On cutting down to the gall-bladder I found it empty; its walls were much thickened by previous inflammation; there was no obstruction of the hepatic and common ducts, they seemed to be in a perfectly healthy condition. The liver was large, at least one-quarter larger than normal, dark in color, and hard to the touch. The presence of this enlarged liver, in connection with the facts that the man had been a steady and at times a hard drinker, and that he gave the history of having contracted syphilis in his early adult life, led me to suspect the final stages of cirrhosis. I therefore attached the omentum, which seemed to be in a perfectly healthy condition, to the abdominal wall, before closing the incision.

The patient recovered from the operation without incident and was very much improved for almost a year; so much so that he returned to his work, which was that of a blacksmith. During this time he took no alcoholic drinks whatever and was temperate in his eating. At the end of eleven months from the time he left the hospital he again consulted me for a severe train of gastro-intestinal symptoms. He could take nothing but the lightest kind of food, which caused severe pain in his stomach and bowels. There was marked tenderness all over this region, also rigidity of the abdominal muscles. The bowels were obstinately constipated, and his digestion finally failed altogether; he wasted away to a mere skeleton, and died eighteen months after the operation.

At the post-mortem examination there was found a strong fibrous adhesion of the omentum to the abdominal wall, and this adhesion was richly supplied with blood-vessels. To the establishment of this collateral circulation was probably due the absence of ascites. The liver was much reduced in size, light in color, and hard. A portion of the gland was sent to the microscopist, who pronounced the condition one of chronic interstitial hepatitis.

A large portion of the omentum was thickened and quite hard to the touch, thickly studded with bead-like deposits. This condition the microscopist pronounced due to tuberculosis. It is rare that an opportunity is afforded to note so closely the pathological conditions existing in the early stage of this disease, as in the above case, and I think it furnishes convincing evidence of the relationship existing between the two conditions—hypertrophic and atrophic cirrhosis of the liver.

The presence of tuberculosis could not be ascribed to an inherited predisposition as both the parents and their families were remarkably free from tuberculous troubles. Many writers, however, speak of the frequency with which cirrhosis of the liver is complicated with tuberculosis.

REPORT OF A SUCCESSFUL CASE OF GASTROTOMY IN AN INFANT.*

By JOHN T. HOWELL, M.D.,

NEWBURGH, N. Y.

W. V. B., aged nine months, was referred to St. Luke's Hospital, Newburgh, November 22, 1901, by Dr. Howell White of Fishkill, with the following history. On the morning of admission, the mother, while dressing the child, suddenly discovered that he had an open safety pin in his throat, and before she could rescue it, the pin had slipped down beyond her reach. The physician who was soon called, administered chloroform and searched the throat with his finger, but unsuccessfully. He then brought the child to the hospital, when we attempted to locate the pin by aid of the fluoroscope. This was also unsuccessful. The baby had refused its bottle from the first and had vomited some bloody mucus several times. Later I passed a rubber tube into the stomach, hoping to dislodge the pin if it had caught in the œsophagus, but it was apparently not lodged there. It was then decided to do a gastrotomy, rather than trust to the natural passage of so uncertain a foreign body as an open safety pin, an inch and a quarter long. The stomach was reached through a median incision, and the foreign body having been located, that portion of the stomach containing it was withdrawn, and the pin was extracted through a small incision. This opening was closed by a double row of Lembert sutures. The recovery was nearly uneventful. The highest temperature, 103° F., occurred six hours after operation, but it fell to 99.3° F. within twenty-four hours. There was no fever after seventy-two hours, and during the same period the pulse fell from 130 to 120, and the respirations from forty to twenty-four. Rectal alimentation with peptonized milk was begun after eight hours, and at the end of fifty-four hours this was supplemented by small amounts of the same given by the mouth. Saline enemas afforded great relief. Hypodermic injections of morphine, gr. $\frac{1}{16}$, were given occasionally during the first forty-eight hours. The bowels moved freely at the end of two days. On December 9 the stitches were removed from the abdominal wound, which was found to be healed. On December 13 the child was discharged from the hospital.

---

* Read before the Newburgh Bay Medical Society.

Largest Recorded Aneurysm of the Heart.—R. G. Curtin reports the case which had been under his observation for two years preceding death. That portion of the autopsy record bearing on the cardiac aneurysm is as follows: "Springing from the left ventricle was a very large aneurysmal sac, which was in close contact with the left side of the chest. The pericardium was thickened and quite intimately adherent to the heart and the aneurysmal sac, but they could be separated by the occasional use of the knife. The mediastinal pleuræ were everywhere incorporated with the pericardium. Near the base of the heart the pleuræ contained soft, yellow lymph, evidently the result of a recent inflammation. The aneurysmal sac formed the apex of the heart. Its walls were about 0.3 cm. thick, and were composed of a dense, light, fibrous material, appearing to the naked eye to be made up of widely separated muscle fibers, demonstrable after the pericardium was removed. When the sac was opened it was found to contain a large amount of blood. In its lower part and half-way up its sides it was coated with laminated clots, about 2 cm. in thickness. After the removal of the black clotted blood the cavity was filled with water. Upon weighing, its weight was found to be 2,850 grams. On emptying the sac and reweighing it, the weight was found to be 1,370 grams less. As a cubic centimeter of water weighs a gram, it will be seen that the cavity had a capacity of 1,370 c.c., or nearly a liter and a half. Two holes communicating with the left ventricle were discovered about the size of a large quill. The apertures were about 1.25 cm. apart, and seemed to be located in a white substance which was undergoing atheromatous change. The inside of the sac was covered here and there with atheroma. In some places calcareous degeneration had taken place. Spicules of this material appeared in the incision, and at one place, in the left side of the sac, a hard plate gave forth a sharp click when struck with a knife."—*Transactions of the Philadelphia Pathological Society.*

The First Treatment of Penetrating Wounds of the Eyeball.—Walter L. Pyle says that in these cases the greatest cleanliness should be exercised, and if there is reason to expect infection copious irrigation with solutions of boric acid (gr. X — ℥ j), mercuric chloride (1 : 5,000) or other antiseptics should be practised. After thoroughly cleansing the conjunctival sac, and the seat of injury, any foreign material or cilia in the external wound should be carefully removed. If the wound is entirely in the cornea, a solution of atropine or eserine is instilled, and a pressure bandage applied; union usually will occur in twenty-four to forty-eight hours. If the iris is prolapsed into the wound, it may be possible to free it by gentle manipulations with a spatula. Otherwise it will have to be seized with an iris-forceps, drawn out of the wound, and freely abscised. Ciliary prolapse should be replaced or abscised, unless it is very extensive. If the sclera is wounded posterior to the ciliary region any prolapsed vitreous should be abscised. The author gives directions for removal of foreign bodies in the eye.—*International Medical Magazine.*

A Case of Acquired Deaf-Mutism.—Mayo Collier reports the case of a girl of nine years, who at the age of three years began to lose her hearing and her power of speech. The trouble gradually increased until, when seen by the author, she was absolutely a deaf-mute. Examination of the ears showed within each, in contact with the membrane, a hard inspissated mass of cerumen of old standing. This was removed with some difficulty. The membranes were found to be extremely retracted, somewhat opaque, but otherwise healthy. Politzer's bag was used, and a wash ordered for the nose. The child improved rapidly in hearing and speech, and at the last interview repeated after the mother, whose lips were covered up, several verses more or less correctly and quite intelligibly.—*Medical Press and Circular.*

THE CANCER QUESTION.

IN *The Hospital*, February 15, has been collected a series of statistics relating to cancer, as well as the opinions of various authorities upon the unsolved points in connection with the disease.

The whole compilation provides instructive reading, and in view of the increasing interest which is being everywhere displayed in all that pertains to cancer, some quotations from the same will be pertinent.

Newsholme, writing in the *Practitioner* on the statistics of cancer, mentions that in the five years, 1891–5, this disease was responsible in Great Britain for an annual registered mortality of 712, and in 1896 of 764 to every million of the population. It is almost certain that these figures understate the actual death-rate from malignant disease. Cancer causes more deaths every year than any other disease, with the exception of bronchitis, pneumonia, and phthisis.

According to the figures for 1896, one out of every fourteen men, and one out of every nine women, reaching the age of thirty-five years, dies of cancer. In 1881–90 the average death-rate from cancer of males aged twenty-five years and upwards was 9.49 per 1,000; in 1871–80, it was 6.97 per 1,000 of the population aged twenty-five and upwards.

With regard to the effect of occupation on cancer mortality, Tatham's report is quoted, which, for the period of 1881–90, shows that among all occupied males the comparative mortality figure for cancer was 44, among all unoccupied males, 96. The theory that excessive nervous strain and anxious work provoke cancer does not receive support in the fact that the comparative mortality figure for medical men is only 43, while it is as high as 70 for brewers. The contrast beween lawyers, 60, and clergymen, 35, is great. Chimney-sweepers occupy a supremely high position in mortality from cancer. The low figure for coal-miners indicates that they enjoy a comparative immunity from cancer, as well as from phthisis. He suggests that the high figures against some occupations may be attributed to intemperate habits.

The greater increase of cancer mortality among males confirms the view that the registered increase of cancer mortality is in a large measure only apparent. Between 1881 and 1891 the registered increase of mortality from cancer was 69 per cent. among males and 28 per cent. among females. This is explained by more accurate diagnosis, more frequent autopsies, and the fact that cancer in the male is more frequently internal and difficult of diagnosis than in the female. The question whether cancer is really on the increase could be solved were all deaths accurately certified, and especially if the primary site of the cancer were stated in each case. Major, writing in the *British Medical Journal*, whilst strongly of the opinion that there has been a real increase of cancer, is not prepared to accept the cancer mortality statistics on account of defective death certification. He quotes the fact that during the year 1896 letters of inquiry were sent by the Registrar-General to practitioners with respect to unsatisfactory certificates, which inquiries resulted in as many as 597 deaths being transferred from various vague causes to the cancer list in one year.

The report of the Cancer Committee of the Birmingham branch of the British Medical Association, which appeared in the journal of the Association, states that there are certain more or less well-defined areas in which the mortality is markedly higher than the average, and others in which it is much lower—a damp, ill-drained, water-logged soil is more frequently associated with a high cancer death-rate than a dry, well-drained soil, and that contamination of the soil or subsoil for long periods with decomposing organic matter is a concomitant of, and probably bears a casual relation with, the specially high cancer mortality; that while second and third cases of cancer occur in particular houses with a somewhat greater frequency than can be accounted for by mere coincidence, there is much greater weight of evidence that cancer is found with extraordinary frequency in particular groups of houses, say, in the same street, thus constituting "cancer foci." This may be associated with contaminated soil. Cancer occurs more frequently in old than in new houses, and in districts inhabited for a long time, than in those recently built over.

The report suggests that under certain circumstances the disease may be transmitted direct from one person to another, among those who are constantly in close association.

Roswell Park is convinced that cancer is actually contagious, while D'Arcy Power believes that, under very favoring conditions, it is an infective disease.

The foregoing views touch upon many of the most salient features of the cancer question, and the expression of expert testimony on the matter can do nothing but good.

The trend of opinion in almost every country would seem to point to the initiation of a really vigorous crusade against cancer, but it would be well if these modern knights of science were to take for their motto, *festina lente*, and to resolve on a plan of campaign calculated to bring about the best results before proceeding further.

The fight against cancer must be waged on different lines to that against tuberculosis. The origin of cancer, unlike tuberculosis, has yet to be discovered, and the primary and essential object surely is to collect funds in order to prosecute this search to the best possible advantage.

As was pointed out by Mr. Malcolm Morris in the *Practitioner*, April, 1899, "Collective investigation" of the etiology of cancer should be organized, so that laboratory workers in different parts of the world may be in touch with one another, and exchange views constantly as to progress.

Individualism in science work is good in its way, exciting healthy emulation but organized labor in this particular field of research might yield better results. Whether scientific men of different nationalities would be unselfish enough to regard the matter in this light is perhaps somewhat dubious.

At any rate there can be no disputing the fact that one of the supremely important questions of the day is to discover the origin of cancer, and it is also an undeniable truth that to accomplish this object very large sums of money are needed.

EUTHANASIA

About a year ago suicide was discussed editorially on more than one occasion in the Medical Record and provoked general attention. The subject of suicide has always been of engrossing interest to all sorts and conditions of men.

The latent strain of morbid curiosity respecting matters psychological, which is inherent to a greater or less degree in every human being, is one reason for this manifestation of concern in all relating to suicide.

Every now and then the question comes to the front, and is made the theme of philosophic dissertations.

In England, recently, a particular phase of the same topic has been widely debated.

The *London Spectator*, February 1, contains an article on that form of suicide known as euthanasia, which was suggested by the circumstance of a Deputy in the Saxon Parliament introducing a bill to permit doctors to put patients, whose recovery was hopeless, to death. After dealing with suicide from various aspects, moral and otherwise, the writer in the *English Review* discourses on the matter from the standpoint of the general public and the physician, and, in part, says: "A feeling has sprung up that God cannot have intended the useless torture of any human being, and that, accordingly, to make death easy when it would be exquisitely painful must, at least for the sufferer himself, be justifiable.

"The thesis is seldom maintained in fruit, though Mrs. Oliphant, who was a strong believer in God, openly defended it in 'Carita' in cases of cancer."

With regard to the proposal to legally endow the medical profession with the power to end life in hopeless cases when so desired, the article in the *Spectator* runs as follows: "The world seldom makes mistakes when its self-protection is concerned, and to give such powers to a whole profession would distinctly lessen its security. As a rule, with a few exceptions, doctors are good people, but there are many of them, and some of them must be bad. To give all a legal right to administer poison or demand, without responsibility, would be to arm every profligate heir with a most dangerous weapon. It is not well for the sake of the class itself to trust the power of life and death to any class which must, of necessity, exercise it in secret. It may be said that the power is trusted now, and so it is, but with the usual guarantees, and this additional one, that the rule of the profession is to preserve life when it can. They have a right, when suffering threatens life, to risk life by the use of sedatives sufficient to prevent that threat, but they act always under the restraint of professional opinion, of relatives, and of the law. To remove the last check would be to constitute doctors a separate caste with rights different from those of the rest of the community—never a safe position. The immediate effect would be to create a new professional impression that their business was not so much to avert death as to secure pleasant death—euthanasia—and the question at what point it should be secured would admit of widely different interpretations. The world, we feel sure, even if it ever accepts euthanasia as allowable, will prefer doctors whose respect for life can be trusted as now under all circumstances."

The above remarks brought forth a flood of correspondence, one writer stating that the late Alfred Nobel advocated suicide under legal and medical control, and offered an immense sum of money to found a suicide club on a gigantic scale, where those who were weary of life from sickness or from other causes, could begin the descent of Avernus painlessly and easily, while another correspondent declared that under Edward II. euthanasia could be practised legally by physicians under certain conditions.

The writer in the *Spectator* argues ably—if argument be needed—against legalizing euthanasia, but he takes the situation somewhat too seriously. The granting of such powers to the medical profession is probably as far off as ever it was. The public and the large majority of the doctors will sternly set their faces against the passing of any measure which would grant control over life and death, no matter under what circumstances, to any class, and which would serve, in a manner of speaking, to cast a shadow over that class.

Perhaps in these times of stress and strain, when neurotics and degenerates abound, there may seem to be a greater tendency to advocate such a law as the legalizing of euthanasia than ever before, but it must also be borne in mind that like proposals were made before the commencement of the Christian era.

Another point which was hardly given due consideration in the arguments concerning euthanasia in England is that even if doctors were to be legally invested with the power to end the life of a person stricken with a deadly and painful disease, that there would probably be but few sufferers who would avail themselves of the privilege.

In any case, there can be no doubt that a proposition of the nature of the one advanced in the Saxon Parliament would be as promptly scouted in every civilized country as it was there.

PUBLIC HEALTH BILL

A bill has been introduced in the House of Representatives to establish a board of public health, and for other purposes. The object of this bill, as stated in the preamble contained in the first section, is to create a commission of public health, to be composed of a commissioner and of a representative from each State and territorial board of health, the Surgeons-General of the Army and of the Navy, the Supervising Surgeon-General of the Marine Hospital Service, or such other medical officer from either service as may be designated by the chief thereof, with the approval of the President, to be known as the "National Commission of Public Health," which shall be a bureau in the Treasury

Department, and the duties of which shall be to collect and disseminate information with regard to the prevalence of infectious diseases in this and other countries; to collect and publish vital statistics; to prepare rules and regulations for securing the best sanitary condition of vessels from foreign ports, and for preventing the introduction of infectious diseases into the United States and there spread from one State or Territory into another State or Territory; and, in general, to make investigations, publish information, and formulate rules with a view to the preservation of the public health; and to perform such other duties as may, from time to time, be prescribed by the Government authorities.

The bill contains thirty-one other sections, which cover all the duties which might be supposed to come within the province of a national board of health.

It, however, would seem—according to the provisions of the bill—that by far the greater part of the work which will fall to the lot of the proposed new board is that concerned with the prevention and spread of infectious diseases and with quarantine matters.

The Marine Hospital Service, by the thorough manner in which it has performed these duties, has made for itself an enviable and world-wide reputation, and would it not be wiser to enlarge the scope and increase the staff and emoluments of a long and well-tried body of men, than to a large extent merge their offices in the suggested new board.

Without prejudice, it appears that the formation of a commission of public health on the plan sketched in Mr. Ray's bill is unnecessary.

THE AMENDED VACCINATION ACT FOR NEW YORK STATE.

This act, introduced into the New York State Senate by Mr. McCabe, has been read twice and committed to the Committee on Public Health.

Its provisions contemplate far more stringent regulations with regard to the enforcement of vaccination than are at present in force.

The vaccination of school children is strongly insisted upon; the trustees or other officers in charge of schools may adopt a resolution excluding children and persons not vaccinated from schools, but ten days' notice shall be given of the adoption of such a resolution, by means of posting copies of the same in public and conspicuous public places within the limits of the school government to the effect that provision has been made for the vaccination of children who desire to attend school, and whose parents or guardians are unable to obtain vaccination for them on account of poverty or for other valid reasons.

The Board of Health of each city or town is required to furnish the means of free vaccination or revaccination to all the inhabitants thereof, and can enforce the fulfillment of this measure, whenever in the opinion of said board the public health and safety demands such action.

The local boards of health are invested with the power to quarantine for fourteen days any person who refuses to be vaccinated.

Principals of schools, colleges or universities, superintendents of almshouses, State reform schools, industrial schools, hospitals and the like, commanding officers of the National Guard, proprietors or managers of manufactories or of business houses, heads of police or fire department of any city, or public and municipal officers of any kind, are required to take care that no person shall remain under their charge or in their employ who shall not have been successfully vaccinated within a period of five years, except upon presentation of a certificate, signed by a registered physician, stating that he has twice vaccinated said person without success and that there exists vaccinal insusceptibility.

The act in its amended form is both comprehensive and binding and would seem to leave no loop-hole for escape from vaccination.

With the regulations as regards schools, hospitals and any place in which a number of persons are gathered together in more or less close contact, none but the prejudiced against vaccination can find fault.

The clause in the act which accords the boards of health the power of quarantining may perhaps be regarded by the strenuous objectors as a somewhat arbitrary measure and an infringement of the rights of citizenship.

However, if the matter be pondered upon without bias, it will be seen that in the framing of this regulation the good of the many is the first consideration. A person who has been exposed to the contagion of smallpox is clearly a public menace, and whatever may be his own opinions on the subject, he should not be allowed to parade them to the danger of the entire community.

The efficacy of vaccination as a safeguard against smallpox and the need of revaccination at certain periods has been abundantly proved over and over again—the experience of Germany has conclusively demonstrated this fact, and although there are some who in the face of the strongest evidence still refuse to attribute any virtue to vaccination, nevertheless they must for the common weal be compelled to yield to the will of the majority.

If vaccination is to be made strictly compulsory, then it would seem necessary, in the natural order of things, that free vaccination should be available to all.

On the whole, the amended vaccination act meets the exigencies of the situation in a satisfactory manner, and deserves the support of the medical profession.

Philadelphia Neurological Society.—At a stated meeting, held February 25, Dr. F. X. Dercum read "A Memoir of the late Dr. John T. Eskridge." Following this Dr. Adolf Meyer, Director of the Pathological Institute for the New York State Hospitals, delivered, by invitation, an address entitled "Conditions for Psychiatric Research," in the course of which he outlined the course of work that he hopes to pursue in connection with the new position to which he has recently been elected. He dwelt especially upon the coordination necessary between clinical study and postmortem observation, and he made an earnest plea for full and careful records of cases, in order that their distinctive features may be established and a practical scheme of classification worked out. At the close of the meeting a reception was tendered Dr. Meyer at the University Club.

MEDICAL HOLDERS OF MEDALS OF HONOR IN THE ARMY.

A board of officers of high rank, headed by Major-General McArthur, which has recently been engaged in an investigation of acts of heroism performed by officers and men of the United States Army during the war with Spain, the Philippine insurrection, and the expedition against Pekin, has found that but ten officers of the entire army should be awarded a medal of honor, the highest distinction in the power of the authorities to bestow. The list of the officers so honored is headed by the name of First Lieutenant George W. Mathews, assistant surgeon, United States Army, the medal being granted him for "most distinguished gallantry in action near Porac, Luzon, P. I., October 29, 1899, in attending wounded under a severe fire of the enemy, and seizing a carbine and beating off an attack upon wounded officers and men under his charge." Dr. Mathews is a native of Massachusetts, and was appointed to the Army from that State.

Besides Assistant Surgeon Mathews, four other medical officers of the Army, now living, have been granted medals of honor, which correspond, in the circumstances under which they are awarded, to the coveted "Victoria Cross" of the British Army. These officers are: Col. B. J. D. Irwin, who received his medal for "distinguished gallantry in action against hostile Apache Indians," while voluntarily in command of a body of troops; Lieut.-Col. H. R. Tilton, for "distinguished gallantry in action against Indians . . . where he fearlessly exposed his life and displayed great gallantry in rescuing and protecting the wounded"; Major J. K. Corson, for "most distinguished gallantry in action near Bristol Station, Va.;" Capt. (now Brigadier-General) Leonard Wood, for "distinguished conduct in the campaign against hostile Apache Indians during the summer of 1886."

But one hundred and ten medals of honor are now held by living officers, of which number five have been awarded to army surgeons. Considering the relatively small number of medical officers of the Army compared with officers of the line, and the fact that the duties of the former largely require their presence where there is no opportunity for the performance of acts of gallantry in action for which, under the law, such medals can alone be awarded, such a showing speaks volumes for the heroism of the medical men in the Army. In the British Army it is said that, in proportion to its members, a greater number of Victoria Crosses—given for "valor" only—have been awarded to members of the Royal Army Medical Corps than to those of any other branch of the service.

ANNUAL REPORT OF THE STATE BOARD OF EXAMINERS OF NEW JERSEY.

The State Board of Medical Examiners of New Jersey has been in existence since 1890, and has every reason to look back with pride upon its record during that period.

By means of the provisions of the law which brought this body into force, definite minimum requirements, preliminary to medical practice, have been established, which are of a higher standard than any heretofore existing since laws regulating medical practice in New Jersey were first enacted.

Its labors, too, in the interests of public health have been attended with much success.

The Board of Medical Examiners has, by the enforcement of stricter laws, improved the status of the profession, diminished quackery, and made it imperative that its licentiates possess a reasonable knowledge of modern medicine and sanitary science.

It is the duty of the Board of Medical Examiners to enforce compliance with the statutory educational requirements of the State, to examine approved applicants for a State license and to issue a certificate of license to those who attain the average that the State demands. This course determines the merits of the applicant for license, and places the profession of the State upon a higher and more equal footing than could otherwise be done.

During the year just gone by the Board has examined eighty-seven applicants for medical license, sixty-three of whom were licensed and twenty-four rejected, making the percentage of rejections 27.58; twenty-three applicants for midwifery license were examined, sixteen of whom were licensed and seven rejected, making the percentage of rejections 30.

New Jersey has set a good example to many States of the country by the excellence of her laws regulating the entrance to a medical career, and has done more than her share towards gaining the object desired by the medical profession generally, of establishing a uniform medical standard in every state of the union.

CIGARETTE SMOKING.

The question of the harmfulness of cigarette smoking is continually coming to the front. Dr. H. F. Fiske, Principal of the Northwestern Academy in Evanston, Ill., has recently stated that only 2 per cent. of those addicted to cigarette smoking in the school had been able to reach the first grade, while in the lowest grade there was a percentage of such smokers of 57.

A mass of evidence has been brought against the cigarette as a most injurious factor in undermining the health, and especially of seriously affecting the nervous system of persons accustomed to smoking them to a large extent.

There can be no doubt that cigarette smoking is exceedingly harmful to the young, and probably smoking of any description in adolescence or adult age is calculated to be opposed to sustained mental effort.

That, however, cigarette smoking in itself is more harmful than are the other modes of using tobacco has never been proved; indeed, the experience of those who have made a study of the matter points to an opposite conclusion. The experiments made by the Health Department of Chicago, some five years ago, failed to reveal any of the peculiarly insidious and noxious properties in several brands of cigarettes examined, which it is often stated they possess, and the analysis undertaken in the laboratory of the *London Lancet* three years ago, of many brands, both American and English, reached similar results.

Smoking, when young, is harmful in many ways, and undoubtedly, as Dr. Fiske says, tends to weaken and deaden the mental faculties.

For this reason, therefore, cigarette smoking is to be condemned in the young, and not because the cigarette *per se* is especially injurious.

INDECENT MEDICAL ADVERTISING IN DAILY PRESS.

There is such a general subversion of the ethical to the commercial by the editors of the newspapers of this country, that the action taken by Mr. Frank A. Munsey, who recently purchased and reorganized the *Washington Times* is worthy of special commendation and sets an example for good which it is much to be hoped may not be unheeded by other editors. In an announcement to the public, Mr. Munsey says: "There is another way of keeping a paper alive when it is not on sound business lines, and that is by running a lot of disreputable and shameful advertising—advertising that ought to put to shame any self-respecting publisher. I refer to a class of so-called medical advertisements that are carried by most of the newspapers of the country—even the respectable papers—but which advertisements are indecent and vile, and which the Post Office Department should compel publishers, regardless of their avarice, to drop."

Following out his ideas, Mr. Munsey has eliminated all advertising matter of this sort from his paper. This action has, undoubtedly, resulted in considerable financial loss, as the *Times* was formerly a conspicuous sinner in respect to the publication of advertising matter of a disreputable character, and it is much to be hoped that this loss may be more than offset by an increased circulation among the decent and cleanly-minded of the community. There is no doubt that suggestive "medical" advertisements of aphrodisiacs, specifics for venereal diseases, preventives of such diseases and of conception, "female regulators," offers of professional services to "ladies in trouble," and the rest of the class, form one of the greatest menaces to public health and morals. They directly incite to vice by promising immunity from its consequences, which they thrust before the notice of the young and innocent. As suggested above, the whole problem is one that should receive the attention of the Post-Office authorities, who have it in their power to prevent this insidious debauchery of the public morals The forcing out of advertisements of this sort from the public prints is one of the first tasks to which a politically-united medical profession should set itself.

Military Hygiene at West Point.

It is understood that, at the direction of Secretary Root, the academic faculty at West Point is now engaged in a consideration of the course of study given the cadets, with the purpose of adding a course of instruction in military hygiene to the curriculum. This addition is strongly favored by the Superintendent, Col. A. L. Mills, who, with other progressive line officers, believes that the object lessons of the sanitary deficiencies of line officers during the war with Spain should not be disregarded and that the scientific and technical training of the cadets should, if necessary, be cut down so as to permit of their proper instruction in the care of troops. Col. Mills is said to believe that military efficiency depends upon the attainment of four great essentials—suitable armament, proper food, efficient transportation service and careful sanitary government—and to favor a course of instruction in practical military hygiene to the cadets extending over not less than thirty hours in each academic year. His broad-minded attitude in this respect is in marked contrast with that of previous Superintendents of the Military Academy, who officially opposed the repeated recommendations of the Board of Visitors that such a course of instruction should be established, and his efforts will meet with the hearty approval and support of the medical profession and of the country at large. It has always seemed to us as if the preservation of the health and efficiency of his own forces by a general was second only in importance to his destruction of the army of the enemy, and that the accomplishment of the former was one of the chief factors in bringing about the latter result. Unnecessary suffering and mortality from preventable disease has always appeared to us to be the result of bad generalship quite as much as poor organization and strategy. The public at large has rapidly come to this way of thinking and in the future will be slow to excuse sanitary deficiencies in commanding officers. We are glad to see that the up-to-date line officers in the army are alive to the necessity of a proper knowledge of hygiene on the part of all those who may have command of troops, and that the traditions of the past, in respect to the study of this most important subject, are to be pushed aside by the progressive administration which is now directing the affairs of the Military Academy.

New Treatment of Leprosy.

The *San Francisco Chronicle* of a recent date has an extremely eulogistic article upon the treatment of leprosy in the Hawaiian Islands by the active principle of the tua-tua shrub.

The journal in question says: "Nearly three years ago the Department of Agriculture sent twenty-seven of the tua-tua plants to Dr. Carmichael, United States Marine Hospital Surgeon then at Honolulu, but now here. The plants were set out in the experiment station grounds in Honolulu, were they flourished, waxed green and produced many buds. With the plants came statements from Venezuela—their home—that leprosy had been successfuly treated with the extract. Dr. C. E. Camp, assistant in the bacteriological laboratory of the Board of Health of Hawaii, has been experimenting on lepers ever since the receipt of the shrub.

In Tahiti really wonderful advance toward the cure of leprosy has been achieved by the use of the shrub, but in Hawaii it has been difficult to induce the lepers to undergo the treatment. The use of the medicine is generally accompanied by severe colic, and the Kanakas will not submit to the pain, even though a promise is held out of a partial cure of their terrible affliction.

The lepers are free to accept or refuse treatment, and cannot be forced to take the medicine. A Portuguese in Honolulu, who had leprosy, was given the tua-tua, and, according to Dr. Camp, shows absolutely no symptoms of the disease now.

Curiously enough, the Board of Health of Hawaii is seemingly unwilling to aid Dr. Camp in his experiments, or even to permit him to treat those lepers under the care of the board. President Sloggett of the board when asked as to this, said: "The Board of Health of Hawaii has invariably turned down requests to be allowed to experiment with leprosy cures. We have done this because the owners of cures were invariably proprietors of patent nostrums, who hoped to sell their manufactures by getting the indorsement of the board. We, of course, would be pleased to see the discovery of some cure of leprosy, but I doubt if any such cure will ever be found."

The newspapers of Honolulu have taken the matter up, and in vigorous terms have urged that the Board of Health give Dr. Camp every opportunity for investigating the merits of tua-tua.

Thus the *San Francisco Chronicle:*

"It would be interesting to learn upon what grounds the prophylactic qualities of tua-tua in the treatment of leprosy are based. Are there any definite proofs that leprosy has been sucessfully treated by the drug in Venezuela and how many cases has Dr. Camp treated with benefit to the patients in Honolulu?

"There should be no great difficulty in ascertaining these facts, and if it can be decisively shown that even partial relief from the disease has been derived from the administration of tua-tua, then no restrictions should be placed upon investigations with regard to [illegible]

In the meantime, and in default of definite information it would appear that the stand taken by Dr. Steggett is distinguished by sound common sense."

Buffalo's Experiment in Dealing With Vice.

It is stated that the ministers and police of Buffalo have reached an agreement with regard to dealing with vice, by which disorderly houses are to be restricted within certain limits, and all public thoroughfares to be kept free from the vicious element.

This new departure on the part of the administration of Buffalo is not, however, without a previous example in this country.

For twenty years, according to a correspondent to the *New York Evening Post*, there has been a like arrangement in Minneapolis, Minn. All the saloons there have been, and they are now, in an area confined to six blocks in width from the Mississippi River on each side, and other questionable places in a narrower limit. This district is regularly patrolled by the police, and keepers of houses of prostitution are regularly fined.

The plan is declared to have answered excellently in Minneapolis.

Regulation of vice in the large towns of the European continent is conducted on somewhat similar principles, the houses of ill fame are, as a rule, confined to a certain district and are subjected to strict medical and police supervision.

Such a system undoubtedly has its merits, and, in a modified form, might act well in New York, where a large part of the population is ignorant and of vicious tendencies.

The Committee of Fifteen have deserved well of the community by their efforts to control prostitution, and will doubtless watch the results of Buffalo's experiment with great interest.

The question of vice in all its forms, and especially of prostitution, of course closely concerns the medical profession, who naturally know better than any other class the evils which are incurred by it, and who would gladly welcome any movement calculated to suppress or repress its worst features.

Tuberculosis in Havana.—The Health Officer of Havana, Major W. C. Gorgas, Surgeon U. S. Army, has recently given much attention to the prevention of the spread of tuberculosis in that city. A sanitary census taken of the city shows the existence of 1,187 cases of tuberculosis, and these have been urged to apply to dispensaries as out-patients for relief, sleep with bedroom windows open, avoid confining occupations, and take proper precautions relative to the disposal of the sputa. Special attention has been given to the cigar manufactories in this respect, particularly since tubercle bacilli were found in cigars which had been made by a consumptive. To this end, cigar workers are required to moisten the tips of cigars, in finishing them, with sponges, instead of with the lips, as was formerly done, and work benches are placed so as to face the same way instead of toward each other. The public reader, a peculiar institution common to all Cuban cigar factories, who is hired to read newspapers, novels, etc., to the hands while at work, will in the future be required to devote a portion of his time to reading matter relating to elementary hygiene and the prevention of disease. The work is essentially educational and persuasive rather than coercive, and is meeting with hearty support from the Cubans.

News of the Week.

Proposed Increase of Medical Corps of Navy.—Recommendation has been made by Surgeon General Rixey of the Navy that the Medical Corps of the Navy be increased by forty medical officers, this increase to be made by the addition of fifteen surgeons and twenty-five assistant surgeons. Owing to the increase in the size of the Navy, the greater number of ships in commission and the large amount of time lost by medical officers in changing station between the United States and the Philippines and other outlying stations, Surgeon-General Rixey finds considerable difficulty in furnishing proper medical attendance. He believes that the addition should affect the higher as well as the lower grades, and points out that the senior passed assistant surgeon has been in the service for twelve years. His recommendations have been approved by the Secretary of the Navy and forwarded by him to Congress, with the recommendation that the necessary legislation be enacted.

Philadelphia County Medical Society.—The stated meeting, held February 26, was devoted to a symposium on cholecystitis. Dr. Joseph McFarland presented a communication on "The Pathology of Cholecystitis," Dr. Joseph Sailer one on "The Etiology and Diagnosis of Cholecystitis," Dr. J. Chalmers Da Costa one on "The Surgical Diagnosis and Treatment of Cholecystitis," and Dr. Solomon Solis-Cohen one on "The Medical Treatment of Cholecystitis." The discussion was participated in by Drs. J. C. Wilson, J. H. Musser, Ernest Laplace, G. G. Davis, J. B. Deaver and W. E. Hughes. A resolution was adopted pledging the moral and material support of the Society to Dr. H. M. Righter against whom a verdict was recently rendered with damages fixed at $1,000 for the development of contagious impetigo following vaccination.

Northern Medical Association, Philadelphia.—At a stated meeting, held February 28, Dr. Orville Horwitz read a paper entitled "The Diagnosis and Surgical Treatment of Renal Tuberculosis," and Dr. H. D. Geisler a paper on "The Urinary Changes in Some Cases of Renal Tuberculosis at the Philadelphia Hospital." The discussion was participated in by Drs. Charles P. Noble, J. P. Strittmatter and others.

Pathological Society of Philadelphia.—The stated meeting, held February 27, was devoted to a symposium on the subject of the blood. Dr. Alfred C. Croftan presented a communication entitled "The Ferment-Chemistry of the Blood, with Particular Reference to General Metabolism," Dr. Courtland Y. White a paper on "Diagnosis by Means of the Study of the Formed Elements of the Blood," and Dr. Joseph Sailer one on "Diagnosis by Means of the Study of the Serum Reactions of the Blood."

Fort Named after Dr. Lazear.—Following its policy of naming the posts and fortifications of the country after distinguished members of the Army, the War Department has recently directed that one of the seacoast defences near Baltimore, Md., shall hereafter be known as Battery Lazear. This action was taken, so the order says, "in honor of Dr. Jesse W. Lazear, late an acting assistant surgeon, United States Army, who, while on a visit to Las Animas Hospital, Havana, Cuba, on September 13, 1900, and while collecting blood from yellow-fever patients for scientific study, was bitten by a Culex mosquito and deliberately allowed it to satisfy its hunger, and, as a result, contracted yellow fever, of which he died on September 25, 1900, thus by his self-sacrifice positively determining that the mosquito carries yellow-fever infection."

An American Hospital in Paris.—Mr. Edward Tuck, formerly of Boston and later of New York, but for twenty-five years a resident of Paris, has promised to defray the entire expense of establishing the free American hospital in Paris, announcement of which has already been made, and the ground for which has already been bought in the Passy quarter, in one of the most healthful parts of Paris. The hospital is to be named Franklin Hospital, and besides being built on the latest American model, it will be managed entirely by American physicians and nurses. Mr. Tuck will not only defray the expenses of installing the institution, but he will also donate a sufficient fund to maintain it permanently without outside help. Dr. Magnin will be director of the institution. Building will be begun in the spring, but it is not expected that the hospital will be ready for occupancy under two years' time.

The Journal of Obstetrics and Gynæcology of the British Empire is the somewhat cumbersome title of a new monthly journal which made its appearance in London with the new year. The editor in chief is Mr. Alban Doran, whose name conveys a promise of excellence, assisted by a huge staff of collaborators, most of whom, we imagine, will be content with contributing their names without engaging in any arduous editorial work. The first number is good, and if the succeeding issues are as good the future of the journal is assured.

Innocuous Yellow-Fever Serum.—Dr. Caldas, who enjoyed a little notoriety hereabouts some months ago, while he was making a trial of the Caldas or Bellinzaghi (we never have known exactly which it was) yellow-fever serum in Havana, and whose experiments failed completely, recently laid his case and his grievances before his Brazilian confrères. The National Academy of Medicine in Rio de Janeiro appointed a committee to examine into the alleged virtues of his serum, and the report made was that the serum was innocuous and also inefficacious.

Hospitals for Contagious Diseases.—It is announced that the Health Commissioner will ask for an appropriation to build five hospitals for the treatment of contagious diseases, together with an equal number of disinfecting plants, in this city. One hospital will be provided for each borough.

The Chicago Water Supply.—The Board of Health of Chicago is constantly warning the people of that city against the use of unboiled water. Until now, it is said, there has been no rainfall sufficient to flush the sewers since the middle of last October, and consequently the first flushing that occurs will wash out an immense amount of filth into the lake and river. This will inevitably contaminate the water and render it unfit for consumption unless previously boiled.

More Public Baths in New York.—The Committee on Public Baths of the New York Association for Improving the Condition of the Poor recently sent a communication to the President of Manhattan, suggesting various plans for the construction and maintenance of public baths. The committee advocates the construction of sixteen bath buildings in various parts of the city; plans were presented.

War on Mosquitos.—The New Jersey House of Assembly has appropriated $10,000 to meet the expenses of an extensive and well-considered plan of campaign looking to the extermination of mosquitos, especially anopheles, in that State.

A Dental Practice Bill has been introduced in the New York State Legislature providing that no degree in dentistry shall be conferred in this State unless the candidate has satisfactorily completed a three-year course in an institution registered by the regents or has had five years' actual practice in operative and mechancal dentistry subsequent to the registration of his certificate as a student, and passes an examination to the satisfaction of the Board of Examiners.

Distribution of Charity Fund to the German Hospitals.—The German Charity Ball Committee has apportioned $10,000 of the receipts of the ball held January 23 among the various institutions, as follows: German Hospital, $1,700; German Society, $1,250; Isabella Home, $1,050; St. Francis Hospital, $1,050; St. Mark's Hospital, $1,050; Poliklinic, $1,050; Wartbury Home, $1,050; West Side Dispensary, $900, and German Ladies' Society for the Relief of Widows and Orphans, $900.

Total Abstinence Hospital.—The articles of incorporation of New York Red Cross Hospital, approved recently by the State Board of Charities, contains the following sentence: "Alcohol, as alcohol, or in any of its forms, shall never be used in the said hospital for internal medication or as a beverage." The incorporators of the hospital are: William T. Wardwell, *President:* John S. Huyler, Dr. A. Monae Lesser, Bettina H. Lesser, Allen Wardwell, Orleans Longacre, John P. Faure, Edward R. Johnes, Max W. Kraus, Alfred L. Manierre and William A. Gans.

A New Building for the Ophthalmic and Aural Institute.—Work will soon be begun upon the foundations of a new building for the New York Ophthalmic and Aural Institute, now located in East Twelfth Street. The new hospital will be at the corner of Sixty-fourth Street and Central Park West.

Influenza is prevailing to a greater extent than for several years past in London, where it has caused a decided rise in the death-rate. Many prominent men in the various walks of life are prostrated, and business is seriously impeded in many establishments owing to the absences of clerks and others down with the grip.

Medical Society of the Missouri Valley.—The fourteenth semi-annual meeting of this society will be held at Lincoln, Neb., on Tuesday, March 20, under the presidency of Dr. Richard C. Moore of Omaha. An interesting program will be presented. The secretary, to whom all the titles of papers to be read should be sent without delay, is Dr. Charles Wood Fassett of St. Joseph, Mo.

International Association of the Medical Press.—A meeting of this association will be held at Monte Carlo on April 7. Delegates to the meeting will be appointed by the various national associations of the medical press. The main subject of discussion will be that of copyright of scientific publications, a report on which will be drawn up to be submitted for approval to the plenary reunion of medical journals, the Second Internationl Congress of the Medical Press, to be held in Brussels next autumn. The question of the establishment of an international medical news organization will also be discussed at the Monte Carlo meeting. Communications regarding this meeting should be addressed to Monsieur R. Blondel, Boulevard, St. Germain, 93, Paris, France.

The Intercolonial Medical Congress of Australasia was held at Hobart, Tasmania, on February 17-22, under the presidency of Dr. Gamaliel Henry Butler of Hobart.

Typhoid Fever in Michigan City.—An epidemic of typhoid fever prevails in Michigan City, Ind. Two hundred cases of the disease are reported to be in existence there. Besides the typhoid fever epidemic. 2,000 cases of winter cholera have developed since the middle of December in a population of 17,000, according to the report of the State Board of Health. Several deaths have occurred, and suits have been brought against the city for damages, as it is charged that the epidemic is due to preventable contamination of the water supply.

The Texas State Medical Association.—The time and place of meeting of this association have been changed from El Paso, April 22-25, to Dallas, May 6, 7, 8 and 9.

The Nathan Hatfield Lewis Prize.—A committee of the College of Physicians of Philadelphia announces a prize of $500 to be awarded to the author of the best essay embodying original observations or researches on "The Relation between Chronic Suppurative Processes and Forms of Anæmia," submitted on or before March 1, 1903. Essays must be typewritten, designated by a motto or device, and accompanied by a sealed envelope bearing the same motto or device, and containing the name and address of the author. No envelope will be opened except that which accompanies the successful essay. Unsuccessful essays may be reclaimed by their respective writers or their agents within one year. The Committee reserves the right not to make an award if no essay submitted is considered worthy of the prize. The competition shall be open to members of the medical profession and men of science in the United States. The original of the successful essay shall become the property of the College of Physicians. The trustees shall have full control of the publication of the memorial essay. It shall be published in the *Transactions* of the College, and also, when expedient, as a separate issue. The essays offered in competition may be sent to Dr. J. C. Wilson, 219 South Thirteenth Street, Philadelphia, Pa.

Victoria University in England is, it is said, about to suffer dissolution. Liverpool insists on having a university of its own, and general opinion seems to indicate that Leeds and Manchester must of necessity claim similar action for their respective centers. This premature disintegration is much deplored by many in the best position to judge of its probable detrimental effects on educational progress.

"The Woman's Medical Journal" has appeared in larger form with the beginning of the year, the old magazine form having proved inadequate. Dr. Elizabeth Dunn has been added to the editorial staff, having charge of a new department of Mental and Nervous Diseases. Dr. Eliza H. Root remains in editorial charge. We congratulate our esteemed contemporary on the well-deserved prosperity to which its improved appearance bears evidence.

A New French Hospital in New York.—The French Benevolent Society of this city is about to build a new hospital on Thirty-fourth street, a block west of the present location. The hospital will be of red brick and limestone, seven stories in height, eighty-four feet wide and ninety-eight feet in length. Each of the wards will have a sun parlor in the rear, and there will be a large roof garden. The present hospital building and the lot on which it stands has been sold.

The Chicago Eye, Ear, Nose, and Throat College.—At the annual meeting of this college, held February 10th, the following were named as the board of directors for the ensuing year: *President*, Dr. W. A. Fisher; *Vice-president*, Dr. A. G. Wippern; *Secretary*, Dr. J. R. Hoffman; *Members*, Drs. Thomas Faith and H. W. Woodruff.

Obituary Notes.—Dr. ERVIN ALDEN TUCKER of this city died on March 3, after a short illness of pneumonia. He was born in Attleborough, Mass., February 2, 1862. He was a graduate of Amherst College and obtained his medical degree from the College of Physicians and Surgeons, New York, in 1889. After study abroad he returned to this country, and was for a time resident physician in the Sloane Maternity Hospital, becoming later assistant attending physician to the same institution. He was a member of the Medical Society of the County of New York, the New York County Medical Association, the Academy of Medicine, the Obstetrical Society, the West End Medical Society, and the Society of the Alumni of the Sloane Maternity Hospital. A widow survives him.

Dr. EDWARD MOTT MOORE of Rochester, N. Y., died at his home in that city on March 3, at the age of eighty-eight years. Dr. Moore, when in active practice, was one of the best known surgeons of this State, and was a prominent member of the American Medical Association. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1838. He was one of the organizers of the New York State Medical Association. In Rochester he was always active in public works, and was known as the father of the Rochester parks, because of his successful efforts to beautify them.

Dr. CONRAD MUND of this city was drowned by the upsetting of a boat in the Great South Bay on March 2. He was graduated from the College of Physicians and Surgeons, New York, in 1900, and subsequently served on the house staff of the Paterson, N. J., General Hospital.

Dr. ELIZABETH B. WAKELEY died on February 27, in Orange, N. J., where she was visiting. She had been a practising physician in New York State for more than thirty years. She was born in Connecticut seventy years ago, but had spent most of her life at Levanna, on Cayuga Lake, N. Y. She is survived by her husband and three adult children, two of whom are physicians.

Dr. ALICE EWING, of Chicago died at Kenosha, Wis., on February 26, aged fifty-two. She was graduated from the State Normal School at Whitewater. After teaching five years she was graduated from the Hahnemann College in 1887, and from the Northwestern University Woman's Medical School in 1894.

Dr. JOSEPH A. BOOTH died on February 26, at his home in this city, from heart disease, after an illness of several months. He was born in Baltimore, Md., sixty-two years ago. He studied medicine in this city and became a general practitioner. For many years he made his home at Long Branch, N. J., but abandoned his practice about a year ago, and had since lived quietly in this city.

Dr. ARTHUR T. MUZZY of this city died March 4 at the Presbyterian Hospital of heart disease. He was born in 1851 in Madura in southern India, where his father was a missionary. He was graduated from Amherst College in 1874, and from the College of Physicians and Surgeons, New York, in 1879. At the time of his death he was president of the Charity Hospital Alumni Association. He had been for nine years assistant surgeon of the Eye and Ear Infirmary. He was also a member of the board of managers of Christ Hospital in Jersey City, and consulting physician at the Isabella Heimath for Aged Couples. Dr. Muzzy was a skilful ophthalmologist and a genial gentleman, and the news of his death will come as a sad blow to his many friends and admirers in the medical profession of this city.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

IMMORAL ADVERTISING—PATHOLOGICAL SOCIETY—OBSTETRICAL SOCIETY—THE "STOMACH CHAMBER"—CANCER AND VEGETABLES—SMALLPOX NOTES—OWENS COLLEGE—ANOTHER V. C. FOR AN ARMY SURGEON—INQUESTS.

London, February 14, 1902.

The evil of immoral advertising is being brought before the public in consequence of the fuss made by the *Daily News* over its new management. Through the Press Association it has sent successive items of information about its entirely new management, which, after all, seems not more new than many an entertainment advertised in similar terms. The chief point is that Mr. Cadbury of cocoa fame, who became chief shareholder when the paper went pro-Boer, has taken over the entire financial responsibility, and appointed a new editor and a new general manager. Mr. Cadbury is a Quaker, and as such, opposed to all war, but that is no reason why his paper should always blame his own country, and support its enemies. Perhaps he perceives this, for he has stated he disapproves "a policy of denunciation," and wishes the paper to be confined to the treatment of great social questions, and to take an "attitude of more moderation."

But the point which is of most interest to the profession is advertising. Gambling and turf news and advertisements are to be excluded—a welcome sacrifice to principle which I fear few will follow, for the increase of the gambling spirit is notorious, and is greatly stimulated by the newspapers. But what about quack advertisements? Some of these are thinly veiled incitements to immorality and crime, against which the medical press has vainly protested. Surely Mr. Cadbury will admit that nothing could be worse than these, and he can scarcely be ignorant of them. The other quack class which offers cures for every ill that flesh is heir to cannot have escaped his notice, for the *News* has been nearly as bad as any of the cheap papers. Next month it is to come out under the new control, and perhaps—or say possibly—we may see a paper without pages of displayed falsehoods, such as even respectable papers like the *Daily Mail* and *Daily Express* do not disdain to circulate as advertisements.

But there are greater sinners than these—to wit, the religious papers—and just now they are exhibiting the most barefaced hypocrisy. Many of them absolutely live on quack advertisements, and do not hesitate to commend quack medicines in their other columns. They are not ignorant—their conduct has often been brought under their notice, but they subordinate all to what pays. Yet the majority have long declined to advertise either alcoholic drinks or tobacco. Alcohol one can understand, but why tobacco? The clergy of all denominations smoke. Many, indeed, take alcohol, and a few defend its use, but there is a strong prejudice against their example, and the evil of drink meets us at every turn. But tobacco—very few are opposed to it, and the clergy, as a class, are inveterate smokers.

A great fight is now going on between the tobacco trusts, and any amount of advertisements can be had for the asking. One of the so-called religious periodicals has broken with the custom and accepted them, to the disgust of their rivals, which are afraid to do so. But I expect they will fall in, notwithstanding the protests of their readers, for it is well known that their subscribers are not numerous enough for financial success, and the prospect of dozens of pages of extra profitable advertisements must be a great temptation to men who see no sin in prostituting the press to shameless falsehood and unclean suggestions.

At the Pathological Society's meeting demonstrations were given of hyaline bodies from a syphilitic lesion; of the arborescent or "inverted fir-tree" appearance in stale-cultures of anthrax; and of Pappenheim's stain for plasma cells. There was also an exhibit of avian filaria from British Guiana. It is not known whether any symptoms are produced by the filaria, nor what are the intermediate hosts. Some experiments with antitoxins, described by Dr. R. T. Hewlett, should be considered by those gentlemen who have been giving them by the mouth, for although the results were not new, they confirm the conclusion from others that antitoxins are not absorbed from the alimentary mucous membrane. Not the slightest protection was conferred on rabbits or guinea pigs against minimal doses of toxins of diphtheria or tetanus by their antitoxins given by either the stomach or rectum.

The annual meeting of the Obstetrical Society was held on the 5th inst., when the officers for the year, nominated by the Council, were duly elected. Dr. Horrocks was re-elected *President* after giving an address in which he referred to some alterations in the rules proposed by the Council, which were adopted by the meeting. One of these is a curious example of the phases of opinion in the Society: instead "of all medical *men*" who have a registerable diploma being eligible for election, it is to read in future "all medical practitioners," etc. The object of the change is to admit women. The most curious point is that the change is only going back to the original wording at the formation of the Society in the sixties. At that time there were no qualified medical women. When they entered the profession the Society signified its prejudice by altering the wording to "medical *men*." Now the women are too numerous to be ignored by this Society, which has been for years thriving on the sale of diplomas in midwifery to uneducated women, and has thereby incurred a large share of responsibility for the midwives' question. In spite of the disapproval of the majority of the profession, this illegal traffic in diplomas continues and tends to maintain a partial qualification opposed to the medical acts, which lay down that a practitioner must be qualified in all three branches. It is strange that the Society has not long since been brought before the courts or the signers of its trumpery certificates been penalized. One would have supposed that such a society would have welcomed *qualified* medical women from the first instead of waiting until they were generally recognized. Perhaps the change is intended to precede a revolution in the shape of the introduction of the *unqualified* women who boast themselves L.S.O. to the Order of Fellows. Few would pity the sellers of unauthorized certificates should they be swamped by their pretended licentiates and "Mrs.——, F.O.S. Midwife" become a common card in the windows of unqualified women.

The other alteration in the rules relates to the privilege of papers read at the Society being buried in the *transactions*. Those not accepted are to be returned to their authors—as ordinary honesty would suggest, and "no longer considered the property of the Society," and all papers read at the meetings may be published in any scientific journal, with the acknowledgment that they were so read.

Professor Birmingham of Dublin described in the *Journal of Anatomy* some two years ago a "stomach chamber" and a "stomach bed," terms which were justified at the Irish Academy of Medicine lately by a specimen hardened *in situ* by formalin. The stomach, when lifted out, showed a distinct chamber bounded above by the diaphragm, below by the small intestines, pancreas, upper extremity of the kidney and transverse mesocolon. This chamber, he said, the stomach fills when distended; when contracted, a portion of the colon presses up in front of it into the chamber. In the healthy adult male he finds the stomach projects downwards, at an angle of 45°, inwards and forwards. When distended, its pyloric extremity tilts upwards and the æsophageal opening is not directly on the lesser curvature, but on the anterior surface. Tight lacing displaces the viscus and alters its relations.

Professor Symington agreed as to the position, but did not see the necessity of the terms "stomach chamber" and "stomach bed," but Professor Cunningham thought them useful and helpful, and said the transverse mesocolon divides the abdominal cavity into a gastric intestinal region.

As I mentioned Dr. Braithwaite's suggestion that salt may tend to cancer, I may add another note from the North. At a late meeting of the Liverpool Medical Institute, Sir W. Banks, in a paper on cancer, mentioned the common notion that excess of flesh meat conduces to the disease.

To this Dr. R. J. M. Buchanan opposed the opinion that it was rather associated with raw vegetables. Holding the parasitic origin, he thought it probable that the parasite was introduced into the body through some lower form of animal life which was in constant association with vegetable food. He had observed that cancer houses were often infested with snails, and the victims indulged freely in salads.

What will the vegetarians say to that? It is not long since they were told the tomato was the dangerous article. Now they are warned against all salads! Perhaps before the summer this idea will be refuted, and we may take salads in due season without fear.

Smallpox continues with variations in the numbers notified, but on the whole fewer than last week. Yesterday there were fifty-four, of which twenty-seven were from the East End. Last night 1,176 cases were under treatment. Three cases have occurred in Dublin. The public have exhibited some alarm, which has driven many to revaccination, and is so far good. But so far this epidemic is much less serious than former ones; *e. g.*, in 1871 nearly 10,000 persons died of the disease. In the last six months there have been 524 fatal cases. There is therefore no occasion for panic.

Liverpool City Council asks for the repeal of the "conscientious objector" clause. There are other indications [illegible] [illegible].

[illegible] is being ordered by a number of local sanitary authorities [illegible] the county.

The London School Board has appointed [illegible] James Kerr, M.D., M.R.C. [illegible]. He had a distinguished career at St. Bartholomew's Hospital and at the University, and he has been for some time medical officer of the Bradford School Board. He has written some good papers on school hygiene and similar subjects. [illegible] the London [illegible] that [illegible] at present [illegible]. A [illegible] of the [illegible] in which [illegible] only last week [illegible] are not [illegible] compulsory authority [illegible] children from school. Are they to be [illegible] as to cast it kindness to expose them to the horrors of smallpox?

[illegible] College is preparing to celebrate its jubilee next month. The Prince and Princess of Wales are to be present. The celebration comes at the moment when Victoria University is threatened with disruption by the determination of Liverpool to separate and have its own university.

Surgeon-Captain Crean is awarded the V.C. He has more than once been reported as "mortally" wounded, but recovered. On December 18 Captain Crean was wounded while at work in the firing line at a range of 150 yards, but continued attending to the wounded until he was hit a second time, and was supposed to be mortally wounded. At one time Captain Crean was a noted athlete.

Two inquests on doctors have been held. One was found severely burned in his room, where he had fallen asleep in front of a large fire. The other was discovered terribly injured on a railway line, on which he appeared to have fallen from a train, a door in which was found open on arrival at the next station.

Two men practising at Clitheroe as dentists, but not registered, were committed for trial on a charge of manslaughter at an inquest on a woman to whom they had given chloroform. One of them said he had given it between 350 and 400 times during the last fifteen months in which he had been in the town. Important questions should arise at the trial, prior to which I refrain from comment.

INOCULATION FOR SMALLPOX:

To the Editor of the Medical Record.

Sir: In these times of smallpox vaccination controversy the following from the *Westminster Magazine* for 1776 may be of interest:

"Inoculation of the smallpox, according to Dr. Douglas of New England, took its rise from the Circassians, a people inhabiting near the borders of the Caspian Sea, who were fond of preserving the beauty rather than the life of their females. They were solicitous of gaining some advantage by every traffic, and for ages past have sold their daughters to the Turks and Persians, and, in order to sell them to better advantage, inoculate them very young. The handsomer they were, the more price they sold.

"From hence this useful operation passed into Turkey, first among the lower class of people. People of fashion at Constantinople, says Dr. Pylarin, did not know it till the year 1701. Dr. Timoni, afterwards, in the year 1713, and in the following year, Pylarin transmitted to the Royal Society, at London, an account of inoculation.

"Among the curious, it was not for some time considered with admiration, till at length, in the year 1721, Mr. Maitland, a Scotch gentleman, though no physician, began the practice in London. From the month of April to December eleven were inoculated with happy success.

"In the spring of the next year, an experiment was made by the king's command upon six children, and not long after upon five others, but not with equal advantage, though, all things considered, with great and laudable success, the Lady Mary Wortley Montague, spouse to our Ambassador at the Porte, bringing the practice from Constantinople, and first introducing it here. These experiments succeeded so happily that, upon good advice, their Royal Highnesses the Princesses Amelia and Carolina underwent the operation, and, by the blessing of God, had a favorable smallpox and recovered. In the same month were inoculated Spencer, the only son and heir of Lord Sunderland, and a certain servant of the Lord Bathurst, but, unfortunately, both died.

"This ill success greatly injured, for a time, the reputation of inoculation, though it did not quite abolish the practice. The new [illegible], like all innovations, soon prevailed, and the other, as usual [illegible], with several [illegible] against it; and in the space of three years throughout all England (as Dr. Jurin, Secretary to the Royal Society, remarked) not more than 477 were inoculated, of whom [illegible] died, and many, after the smallpox, were [illegible] with [illegible] disorders [illegible]. The proportion of these to those who [illegible] of smallpox, [illegible] as appears from [illegible] calculations. The following [illegible] the proportion of those who died [illegible]. At length the practice by degrees grew [illegible].

"But at last, by experience and care, it [illegible] than ever, and still continues, to the saving of some thousand lives. Clean [illegible] healthy, and [illegible] the least quantity of infection, just enough to disturb the blood a little, and without the form of any previous preparation [illegible] will come forth [illegible] need not confine the patient [illegible] day [illegible] the fever [illegible] the latter. I myself have inoculated above forty at Leigh, and not one had a [illegible] symptom or the least ill consequence ensued.

"But there is one [illegible] the practice [illegible] attended it. Though the inoculated thereby escape death, yet by communicating the infection to others who never had the smallpox, great numbers have been thereby destroyed, as the increase of burials in the yearly bills of mortality ever since inoculation came up, but too melancholy prove; to remedy which, and that the great benefit of inoculation may be fully enjoyed, I wish our Members of Parliament, conjointly with other honorable representatives, would offer a bill to the House for proper restraints and regulations to be observed, and to have pest-houses on purpose at proper distances from towns and cities for the inoculated to perform quarantine before mixing again with the multitude, or whatever other ways and means their superior wisdom think fittest; then the great blessings of this new discovery might be freely reaped without danger to others, and many of our most gracious Sovereign's loyal subjects' lives would thereby be happily prolonged, to the great and general good of the nation.

"Leigh, September 13, 1776. J. Cooke."

F. B. Stephenson, M.D., U.S.N.

U. S. Navy Yard, Portsmouth, N. H.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 27, 1902.

Broncho-pneumonia in Epidemic Form.—William Watson McKibben reports the occurrence of this disease in five children in one family. Two died, the other three were removed to a hospital and recovered. Pneumococci and pus organisms were found in their sputum. In cases of broncho-pneumonia at the Babies' Hospital, in which tubercle bacilli were found, Holt also discovered pneumococci, which he regards as explaining the fact that tuberculous broncho-pneumonia cannot be distinguished from the simple form by the symptoms. Osler cites examples of the epidemic form of pneumonia depending on a specific microörganism. The author also witnessed a small infection in 1890 and several epidemics have been seen in Worcester during the past ten years.

Some Points of Value in the Diagnosis of Disease of the Abdominal Organs.—Henry Jackson says that pain is the most unreliable symptom, it being often absent in grave cases of appendicitis and sometimes overshadowed or benumbed by the severity of whatever disease is present. Nausea and vomiting are of great importance, as is the occurrence of obstinate constipation in a patient who has not previously suffered from it. The general appearance is often a guide to diagnosis. Tenderness must be distinguished from pain, and spasm is the most important sign of all, as it is as evident in the unconscious as in the conscious patient. The most valuable sign in the diagnosis of intestinal obstruction is an empty rectum, when there has been no movement of the bowels for several days. Examination of the blood may give important evidence; leucocytosis is almost invariable in cases of acute inflammatory disease with exudation. The Widal reaction is of importance when found, and the blood count is of value in the elimination of malaria, when chills of doubtful etiology are present; in malaria or in typhoid fever the leucocytes are below the normal number. The malarial organisms, if present, determine the diagnosis.

The Significance, Pathological and Clinical, of Abdominal Pain.—Maurice H. Richardson reaches the following conclusions: When a patient has been seized with sudden severe abdominal pain, the pain should not be masked by opiates before the surgeon has seen the case. Previous history, symptoms, and signs must be carefully considered, and careful examination made of thorax and abdomen. If hemorrhage is suspected, the abdomen must be explored; if the patient is in collapse, and the pulse is weak, a preliminary infusion of salt solution should be made into veins or under skin. Exploration should be immediate when pain is excruciating and the abdomen shows signs of infection. The seat of initial pain is a good guide to the incision. The history and signs other than pain must be relied on for exact diagnosis. Were exploration a routine procedure, more lives would be saved. The genuineness of the pain should be tested; the pain of atypical typhoid fever, pleurisy, or pneumonia must be guarded against, and functional disturbance is not to be confused with organic disease. In doubtful cases the surgeon should explore. If exploration is not justifiable the pain is to be controlled by morphine, hypnotics, or even a general anæsthetic. Excepting in a few cases, chiefly of renal and biliary colic, the pain that demands general anæsthesia demands operation.

Journal of the American Medical Association, March 1, 1902.

The Unveiling of the Cell.—In a general discussion of recent progress along this line of study, L. F. Barker emphasizes three facts: (1) The remarkable variety and complexity of the chemical substances given off by the cells to the blood and lymph; (2) The chemical specialization of the various tissues of the body; and (3) The value of chemical and physical conceptions as working hypotheses in the interpretation of life phenomena. He adds that the conception of a chemical differentiation of tissues more divergent even than that which characterizes their morphology promises to be a distinct incitant to further investigation and discovery. Certain it is that aside from the chemical and physical peculiarities common to protoplasm in general, there are a host of special activities localized in the cells of different regions of the organism, the necessary consequence of ontogenetic development and a long phylogenetic history.

Examination of a Genito-urinary Patient by the General Practitioner.—F. C. Valentine lays down the following rules: (1) All genito-urinary examinations should be painless; (2) The operator should conduct no examination unless his arms are bared to above the elbows and his clothing protected by a gown and apron; (3) During every genito-urinary examination the physician should protect his eyes with spectacles—not eyeglasses—even if he has no visual defect (4) Ideal examinations are made in the morning, before the patient has passed his first urine; (5) The amount and character of a urethral discharge can be estimated only by correct technique in expressing the urethral contents; (6) The color of a urethral discharge changes when it dries upon the patient's garments; (7) The meatus should be cleaned before passing urine for examination; (8) The manner of urinating is often pathognomonic; (9) The epithelia found in the urine are indicative of the locality of the lesion; (10) Examination of the urethral adnexa is a necessary part of the steps for complete diagnosis; (11) No instrumental ingression of the urethra should be attempted without most thorough efforts at rendering it aseptic; (12) The technique of striving at urethral asepsis is neither complicated nor difficult; (13) The soft bougie-á-boule is the only instrument that can be used for tactile exploration of the urethra; it is purely a diagnostic instrument; the rigid sound is wholly a therapeutic instrument; (14) Urethroscopy with a modern instrument is not difficult; (15) The general practitioner is perfectly competent to examine the vast majority of genito-urinary cases; (16) Such examinations only exceptionally require extraordinary skill or a large armamentarium; (17) The pathology of genito-urinary disease does not materially differ from that of other affections.

New York Medical Journal, March 1, 1902.

The Value of the Eosinophile Count in the Differential Diagnosis of Human Blood.—O. S. Wightman presents the following conclusions: (1) Eosinophilia may occur in higher percentage in animal's blood than in human blood; (2) The physical condition of the animal whose blood is to be compared may play an important part in the increase or decrease of eosinophiles present; (3) In the specimens examined the polymorphonuclear counts were low and the lymphocytes high, exactly contrary to conditions present in normal human blood; (4) The eosinophile count is not a constant or trustworthy factor in diagnosis, but, on the other hand, is very unreliable and unsatisfactory; and, finally, (5) As a comparative test the eosinophile count is a negative quantity.

A Bougie Removed from the Abdominal Cavity; Ruptured Abdominal Hernia.—Two clinical histories are given by J. T. Johnson. In the first an abortion was produced by the passage of a No. 8 flexible bougie. When the fœtus and membranes came away the bougie could not be found. Severe abdominal symptoms two days later led to exploration of the uterus, into and through which a sound was passed until only the handle protruded from the vagina. It was concluded that the bougie had penetrated the uterus, and was in the abdominal cavity. Exploratory incision showed this to be true, the bougie being folded over and covered by the omentum. The case recovered without incident. The opening in the uterus had become thoroughly closed and could not be found. In the second case an umbilical hernia had ruptured, and several feet of bowel had been out on the abdominal surface and covered with unsterilized cloths and bandages for at least seventeen hours. The parts were cleansed and returned to the cavity of the abdomen. The patient, a woman of fifty-seven years, did well for seven days, and then died, apparently of general septic peritonitis. Her general condition previous to the rupture was bad, and her surroundings unfavorable before she was taken to hospital. The author gives a summary of previously reported similar cases.

American Medicine, March 1, 1902.

Suggestions to Anæsthetizers.—Frank E. Simpson makes the following suggestions: (1) Give the patient your undivided attention; (2) Administer the anæsthetic slowly; (3) Keep the patient's lower jaw forward; (4) Observe extreme caution (especially in chloroform administration) when the stage of unconsciousness is at hand; (5) During deep anæsthesia watch particularly the respiration, but also the pulse, eye, and color; (6) The rolling of the eyeballs from side to side is the first and most easily-observed indication of returning consciousness.

The Treatment of Acute General Peritonitis.—Eugene A. Smith defines acute general peritonitis as a rapidly-spreading inflammation of the visceral and parietal peritoneum due to bacterial infection. In the male, undoubtedly, a vast majority of cases are due to appendicitis, and, in the experience of the writer, this has also been the case in women. According to Treves and others, several causes of peritoneal infection are grouped as follows: Obstruction of the bowels, perforation of typhoid, gastric, and tuberculous ulcers, cholelithiasis, nephrolithiasis, rupture of visceral and other abscesses, and fat necrosis. Bacteriology offers the ideal classification for the forms of the disease, but the clinician cannot yet apply this classification in practice, to determine prognosis and treatment. Thus treatment is uncertain, unless by radical procedures; effectual in the most severe infections of the peritoneum, an attack is also made on the less severe infections. The writer thoroughly believes in the value of sterile decinormal salt solution in the treatment of acute general peritonitis. The solution is heated to a temperature of 110° F., and large quantities are used to flush every accessible part of the peritoneal cavity. From four quarts in early cases to sixteen or twenty quarts in late cases are used, and the process takes from five to fifteen minutes. In draining the abdomen after irrigation for acute general peritonitis, the writer uses Price's aluminum tubes in the pelvis, and gauze wicks in the iliac fossa, behind the cæcum and among the intestinal coils. In these patients the abdominal wound should be left as open as is consistent with retaining the abdominal contents. Silk-worm gut sutures are used to approximate the upper and lower edges of the peritoneal incision, and gauze compresses may be loosely tucked into the gaping wound to hold back the intestines till adhesions can form. A many-tailed bandage may be used to prevent extrusion of the gut. After the operation the anus is dilated to allow the easy escape of flatus. In the postoperative treatment, strychnine is used hypodermically in severe cases. Salt solution is given in all cases, per rectum. Catheterization may be necessary. In severe cases the urine is quite certain to be scanty, and to show albumin and casts. Morphine should be used if the patient is restless, hiccoughing, or in great pain. Whiskey may be given if it can be borne by the stomach. On the third, fourth, or fifth day, calomel may be given, with sodium bicarbonate. Rochelle salt or compound jalap powder may follow this, and a turpentine and glycerin enema may be given later to aid in moving the bowels. Nourishment by the mouth is forbidden for three to six days after operation. Cracked ice or seltzer water in teaspoonful doses is allowed from time to time. Meat broths may be given cautiously on the third day or later. Milk is badly borne, as a rule, and should not be given till the second week of convalescence.

[illegible], March 1, 1902.

Acute Pelvic Suppuration by Conservative Treatment.—[illegible]

Suturing the Head of the Humerus to the Acromion in Old Subcoracoid Dislocation.—[illegible] and the head of the humerus was rotated in the glenoid cavity. But on account of the pronounced tendency to forward displacement, which could not be overcome, the head of the humerus was fastened in the cavity by suturing it to the acromion after a hole had been drilled through the acromion as well as through the head of the humerus. The writer believes this procedure to be better than resection of the head of the humerus. No [illegible] and laceration of the muscles, blood-vessels and nerves is easily avoided.

Ventrofixation; A Suggestion.—[illegible] C. [illegible] [illegible] of the linea alba in the operation. He describes the method of which he approves as follows: (1) Exposure of the sheath of the rectus through a median cutaneous incision two or three inches long. (2) Strong retraction of the skin to one or the other side. (3) Opening the sheath of the rectus about three-quarters of an inch from the median line. (4) Liberal loosening of the rectus from its sheath, and retraction of it as far outward as possible. (5) Opening of the peritoneal cavity. (6) Loosening of the peritoneum behind the linea alba. (7) Search for large vessels at this point. (8) Passage of the sutures as follows: The median edge of the peritoneal wound is seized with forceps and the needle is introduced half an inch away from the middle line; it is next passed through the uterus emerging beyond the median line on the opposite side; it is then passed forward through the peritoneum, previously loosened as described, and then through the linea alba sufficiently deep to secure a firm hold. The two ends are then seized in an artery clamp. The other suture is passed in the same way and both are tied so that the knot is extraperitoneal. (9) Suture of the peritoneum. (10) Restoration of the rectus to its sheath. (11) Ordinary layer sutures close the rest of the wound. Mattress sutures are used in closing the sheath of the rectus, and in such a way that they do not [illegible] on a single bundle but on many bundles of fibers. A retention catheter is inserted in the bladder before the uterus is suspended, and from six to ten ounces of salt solution injected. In this way the [illegible] for fixing the uterus is [illegible].

Philadelphia Medical Journal, March 1, 1902.

The Ice-Pack, and Its Definite Therapeutic Advantages Over Other Methods.—Lester L. [illegible] advocates this treatment in typhoid when the temperature goes above 102.2°. If there is any renal disturbance, hot milk should be given before and after the pack, and at each change of the sheets. If the kidneys are normal, then whisky is given [illegible] before and after the pack. The mattress is covered with a couple of blankets, on top of which is a rubber sheet, over which is another blanket. Thus the body does not have to come in contact with the rubber. A sheet and blanket that have been soaked in water at 70° F. are brought to the bed and the patient is rolled from his warm coverings into these wet ones. Half an hour later, others are substituted at a temperature of 60° F., again at 50°, and lastly at 40° F. At the last two packs, the axillary spaces, the arms and the legs from the middle of the femur down, are covered with cracked ice, packed outside the sheets. By this method the exposure which so often leads to pneumonia is avoided. Hemorrhage and perforation will never be seen. The pack is a nerve sedative and a cardiac stimulant. This method can be carried out in any home.

Two Cases of Adiposis Dolorosa: One in a Man, Complicated by Epilepsy; Another in a Woman, Presenting also Circinate Retinitis.—F. X. Dercum states that of the twenty-[illegible] cases of this disease on record, only three have occurred in men. [illegible] fatty deposit. [illegible] The second case is a woman, aged thirty-three, married and a housekeeper. The thighs are enormously enlarged. The upper and middle thirds of the legs and both upper arms and the upper and middle thirds of the forearms are also enlarged. She complains of extreme tenderness and soreness to the touch over widely-distributed areas. There is no spontaneous pain. She tires very easily. In the left eye there is a circinate retinitis. Both of the cases belong to the localized diffused type of the disease. The greatest part of the deposit in the man is upon the trunk, in the woman upon the thighs. Asthenia is a marked symptom in both patients. The man is subject to epileptic attacks. In both patients there is a marked tendency to discoloration of the tissues from slight injuries.

A Case of Ascites, Due to Hepatic Cirrhosis, Treated by Transplanting the Omentum Between the Peritoneum and Abdominal Wall.—W. J. [illegible] and Geo. W. Spencer report this case. The patient was forty-one years old when first seen by them. Ascites had begun about three months before this time. The personal history pointed to syphilitic infection, and this was supposed to be the cause of the cirrhosis. The liver and spleen were not discovered by palpation. She was put on mixed treatment, and in addition was given hydrochloric acid, nux vomica and cardamom. Paracentesis was performed thirty-two times in fourteen months. The patient was very eager for an operation, and it was at last agreed upon. The object in view was to establish venous circulation through the medium of adhesion between the veins of the omentum and the veins of the anterior abdominal wall, and thus relieve the obstructed vena porta. The operation took only twenty minutes. Recovery was uneventful and in four weeks she was feeling better than for any time during the previous two years. She lived about eight months after the paracentesis being performed twenty times subsequent to operation. Autopsy showed entire absence of right kidney, and the presence of a very large horseshoe kidney on the left side, extending to the right as far as the head of the colon and appendix. Frequent examination of the urine during life had never shown any albumin or casts. The absence of blood in the ascitic fluid and its comparatively low specific gravity, 1010, were factors in diagnosis against the possibility of malignant disease, causing the ascites. The writers do not believe that the horseshoe kidney was in any way a contributory factor to the ascites. The liver was much smaller than normal, and firm to the touch, but not hobnailed. The gall-bladder was moderately distended and, with the ducts, was free of calculi. The writer believes that operation is indicated in such cases and thinks that in this case it prolonged life six months.

The Lancet, February 22, 1902.

Rheumatism as a Cause of Epistaxis in Children.—Sidney Phillips gives notes of ten cases of epistaxis occurring in young children. He believes the association of this symptom with rheumatism to be very common. It was not due in his cases to a toxic effect of the salicylates, for it occurred before the latter were given. The author assigns no cause for the complication, and says he has found no mention of the fact in literature except that rheumatism may cause nose-bleed indirectly through changes set up in the endocardium.

Tetanus Following Revaccination on the Leg; Recovery after Prolonged Use of Chloral Hydrate.—W. Findlay and J. W. Findlay report the case which occurred in the person of a girl of twenty-one years. The operation was done in the usual manner, proved effectual and the patient was doing well when on the tenth day she was exposed to a strong draught. On the twelfth day she commenced to complain, but was not seen by the doctors until the next day. The vaccine wound was covered with a light sloughy mass and did not look well, though it quickly cleared off on the application of a poultice. There was no temperature, but there was rigidity of the muscles of the neck and jaws. The latter symptoms gradually became more and more pronounced and the administration of chloral was begun. It was necessary to continue it for a period of over six weeks, during which time the patient occasionally took as much as 240 grains in the twenty-four hours. Recovery finally ensued.

Burns from Celluloid.—Commenting on the fact that so many articles now in common use are made from celluloid, Alexander Ogston calls attention to the evident fact that celluloid articles of uncertain composition and dangerously explosive quality are everywhere sold and are in constant use, and that the conditions under which they may ignite in varying circumstances cannot be fully inferred from experiments regarding their ignition point made in a physical laboratory; (2) Badly manufactured celluloid ignites at variable temperatures, too low for it to be safely used; (3) It follows that restrictions should be imposed upon the sale of all such articles which do not sustain, without ignition, a temperature equal to that sustained by well-manufactured celluloid; (4) It is worthy of consideration whether all celluloid articles of personal wear and such others as might give rise to fires ought not to be compelled to have the word "ignitible" conspicuously imprinted upon them; (5) If the suggestion to render celluloid incombustible by the addition of some chemical should be practicable it would be the best solution of the difficulty, and such an addition ought to be made compulsory by legislative enactment.

The General Pathology of Tumors.—In the third Erasmus Wilson Lecture C. P. White sums up his conclusions concerning the pathology of tumor formation as follows: (1) Tumors should be classified on a histological basis. The best mode of effecting this is to make use of the threefold basis of cells, tissues, and organs; (2) The rudiment from which a tumor springs may consist (*a*) Of the structures normally present at the point of origin; (*b*) Of an embryonic collection of cells; or (*c*) Of tissues of new formation, the result either of an inflammatory condition or of previous tumor formation; (3) Extrinsic factors play a part in tumor causation, but are not the determining factors—that is, the occurrence or non-occurrence of tumor does not depend on extrinsic factors. In particular, the parasitic theory is shown not to stand a critical investigation; (4) The determining factor in tumor causation is to be found in the intrinsic factors; (5) This determining factor consists in the existence of a condition of unstable equilibrium between the intercellular forces, so that proliferation, once started, is progressive and is not limited by the resistance of the surrounding tissues; (6) The cause of this instability are many and various and may be either intrinsic or extrinsic; (7) Proliferation having started, the cells acquire the habit of growth—that is, the power of independent proliferation which enables them to proliferate in parts of the body in which the condition of equilibrium is stable; (8) Tumors grow by proliferation of their own cells; (9) Tumors do not invariably continue to increase without limit. Under certain circumstances they may cease to grow and may diminish in size or may even disappear completely; (10) Tumor formation is not to be regarded as an isolated process, but is to be considered as one of a group of progressive processes with which it is closely allied. Still less must one form of tumor, such as carcinoma, be considered apart from the others.

British Medical Journal, February 22, 1902.

Hydrogen Peroxide in the Treatment of Lupus Vulgaris and Tuberculous Abscess.—Charles Herbert Gunson declares that hydrogen peroxide is a most effective germicide, yet practically unirritating, and harmless to delicate cells if not used in its full strength. Its mechanical action is also valuable, on account of its effervescence. It is valuable in lupus exedens, also in the healing of chronic or tuberculous abscesses, after their contents are evacuated. It has an excellent effect when sprayed on ulcers and purulent wounds.

Should Milk Be Boiled?—W. B. Ransom says that there is no solid evidence to show that milk raised to its boiling point (110° C. = 233° F.), or to the temperature of boiling water for ten minutes or a quarter of an hour, suffers any diminution of its nutrient qualities. Neither is it probable that, if consumed within twenty-four hours of the heating, it will cause infantile scurvy. The same is true of Pasteurized milk heated to 80° or 85° C. None of these methods renders the milk absolutely sterile, but they do kill most pathogenic microbes (*e. g.*, those of tuberculosis, cholera, diphtheria, and typhoid fever), and if the milk be kept cool and drank within twelve hours of the heating, few or no spores will have developed into bacilli. Pasteurization is probably less reliable than heating to 212° F. for ten minutes, and is also more difficult to carry out. In times of epidemic summer diarrhœa the heating should be prolonged for at least half an hour, and the milk drank within a few hours, or subjected again to the process. Milk should always be drank as fresh as possible.

On the Effects of Forced Feeding in Cases of Pulmonary Tuberculosis and in Normal Individuals.—Noel D. Bardswell, Francis W. Goodbody, and John E. Chapman conclude: (1) That since very large diets gave worse results than those of more moderate amount, the indiscriminate stuffing of all tuberculous patients should be replaced by systematic dieting. The diets as regards amounts and constitution should be determined in each case after due consideration has been given to the respective conditions as regards: (*a*) The activity and extent of disease; (*b*) Amount below weight; (*c*) Digestive capacity; and (*d*) To some extent personal dietetic likes and dislikes; (2) That in view of the bad effects which overfeeding gave rise to in the normal individuals, great care should be taken in the selection of a diet for patients who, as the result of treatment, have reached or passed their highest known weights. When this regain of weight is associated with arrested disease, the original diet found suitable for a person considerably under weight and with active lesions, should be reconstructed more upon the lines of what would be suitable for the same person in perfect health. The lungs do not seem to improve any more upon forced feeding than upon generous diets, and certain uncomfortable symptoms, such as anorexia and vomiting, are met with more frequently in cases having large diets than in those of more moderate amounts.

Deutsche medicinische Wochenschrift, February 6, 1902.

Tertiary Syphilis of the Pharynx.—Levinger emphasizes the importance of the accurate recognition of isolated tertiary syphilitic lesions of the posterior nares and tonsils. When the posterior nares alone are involved, the lesions escape superficial observation, and can be seen only when posterior rhinoscopy is undertaken; for this reason patients whose history and objective symptoms are suspicious should always be examined in this manner. As a rule, the patients complain of sore throat, especially upon swallowing, and frequently this is so severe in nature that food is only sparingly partaken of, and the bodily nutrition is seriously impaired thereby. Headache is a prominent symptom. The ear may become involved through the Eustachian tube and a purulent otitis media develop. The soft palate is often considerably infiltrated, and less freely movable than normal. The voice has a nasal intonation, and in the morning is apt to be very hoarse. If the syphilitic lesion is of any considerable size, the presence of a purulent discharge is added to the above symptoms, and the breath becomes fetid. As a certain amount of such a discharge is more or less frequently swallowed, digestive disturbances, which may become pronounced, are caused thereby. The conjoined administration of potassium iodide and mercury forms the sheet anchor of treatment for this condition. In addition the local application of calomel and orthoform is to be recommended. The author reports a case in exemplification of the favorable results obtained by this method of treatment. Levinger also reports a case in which there was a syphilitic tumor of the tonsil. He believes that the case is unique, and that a similar condition has not hitherto been observed. The diagnosis is practically based upon the enlargement of the neighboring lymph glands and the fact that under the administration of potassium iodide the tumor rapidly disappeared. A syphilitic history was absolutely denied and no other lesions of syphilis were observed.

Myelogenous Leukæmia.—Hans Hirschfeld and Ernest Tobias report two cases of myelogenous leukæmia and bring out interesting points in regard to the blood condition in this disease. The first case was observed for about five and one-half months, when it was lost sight of. The second case was followed to the autopsy table, where it was discovered that pulmonary, pleural, and hepatic tuberculosis was present. It is interesting to note that the pulmonary tuberculous condition was not diagnosed during life, although lung symptoms were present and were regarded as pneumonic in nature. Coincident with the development of the pulmonary symptoms there was a marked fall in the total leucocyte count from 426,000 to 283,300, and it is somewhat remarkable that the probable existence of tuberculosis was not suspected. In this case a tumor of the external ear developed. It was removed and found to be a myeloma. In general, it may be said that the differential leucocyte count in both of these cases was similar in character, but different in detail. In the first case the polynuclear neutrophiles were generally increased. Only on three occasions was their number subnormal. At times they [illegible] from 56 to 60 per cent. of the total number of leucocytes. The highest figures for the eosinophiles were present in the second case, [illegible] per cent. In both cases, however, these elements were subject to great variations, so frequently they were only present in from 1 to 3 per cent. Taking the cases altogether, there were many more eosinophiles in the first than in the second case. The large and small mononuclear leucocytes were much more abundant in the second than in the first case. The counts there showed from [illegible] per cent. of the large and from [illegible] per cent. of the small [illegible], while [illegible] per cent. for the large and [illegible] per cent. for the small were the highest figures [illegible] in the second case. [illegible] myelocytes were more abundant in the first case. The highest figures for these cells were [illegible] per cent. in the first and [illegible] per cent. in the second case. Mast cells were more scanty in the first case. On some days they were entirely absent, and the highest figures obtained for them were [illegible] per cent. In the second case they were absolutely [illegible], the highest figure being [illegible] per cent. The important point brought out by these figures is the fact that in considering the diagnosis of myelogenous leukæmia from the standpoint of the differential leucocyte count, general principles and not figures are to be considered. For staining the blood eosin and methylene blue and Ehrlich's triacid stain were used. The mononuclear cells, both neutrophile and eosinophile, varied greatly in size, many giant and many dwarf forms being observed in the same smear. A few mononuclear cells showed a granule-free protoplasm. In some of the neutrophile and eosinophile the granules were variously colored, and shades varying from a light blue to the normal characteristic color were frequently seen in the same cell. Occasionally peculiar small polynuclear cells were seen which differed from the dwarf forms in that they contained very few granules which stained a deep reddish violet. Some of these contained strongly refractive [illegible] granules, and are to be considered as mast cells. The authors examined the blood in both of these cases for the presence of protozoa, employing the methods of Löwit. They detected the presence of the bodies considered as parasites by this observer, but the same failed to take the olive-green tint which he describes. This, however, may be due to the fact that they used different dyes from those which were employed by Löwit. These forms were observed more frequently in the large mononuclear and polynuclear than in the small mononuclear leucocytes. This is in contradistinction to the findings of Löwit. They do not regard these forms as parasites, but as artifacts and degenerative products. Upon autopsy similar elements were not found in the blood-forming organs. Animal inoculations were conducted by means of emulsions of the spleen, lymph glands, and bone marrow obtained from the second case. Twelve rabbits were thus inoculated. The results were negative. Three died soon after the injection, four succumbed in twenty-four hours to sepsis, and the rest recovered quickly, being subsequently killed and dissected. A hyperleucocytosis of a varying grade was present in every case, but no leukæmic changes were observed in any case in the blood organs or bone marrow.

—*Berliner klinische Wochenschrift*, February 10, 1902.

The Peculiarities of Ear Diseases in Children.—B. Baginsky considers certain factors which influence the development, peculiar characteristics, and sequelæ of ear diseases in children. In the first place the anatomy of the temporal bone in childhood differs from that found in adult life. The petro-squamosal fissure is of considerable size in childhood, and forms a distinct communication between the middle ear and the cranial cavity. A vascular prolongation of the dura mater is lodged therein, and in cases of middle-ear infection forms a ready means of transit by which infective matter may be transported from the locality to the interior of the cranium. In adult life this fissure is practically closed. The hiatus subarcuatus is also much larger in children than in adults, and forms an additional source of danger for the extension of infection from without inward. This liability is still further increased by the fact that in childhood the mastoido-squamosal and tympano-squamosal sutures are not fully closed. The Eustachian tube is much shorter, wider, and more horizontal in children than in adults, and hence is much more capable of transmitting infective matter. It is also certain that the presence of adenoids, which are almost exclusively seen in children, favors the development of middle-ear infection. It is also well known that children have great vulnerability of the nervous system and are much less resistant to all sorts of infections than are adults. This cannot fail to have a certain influence upon the development and course of ear affection. Finally the results of autopsies have shown that the mucous membrane is much more vascular and succulent in childhood than in adult life, and therefore at this age especially susceptible to infection. The preceding conditions account for the great frequency of middle-ear infection in children and the marked tendency to extension to the internal ear and the cerebral meninges. The early recognition of middle-ear infection at this age is therefore especially desirable, as then appropriate treatment may be instituted and serious consequences avoided. In all suspicious cases thorough local examination should be at once undertaken. Especially is this true of the so-called neuralgic or meningeal type of otitis media. This condition at the outset simulates a genuine primary meningitis. Local examination shows the membrana tympani congested and frequently bulging. Whether this form of otitis media is due to direct transmission of the infection to the meninges or is brought about by excessive pressure upon the stapes has not been as yet definitely determined, but it is probable that in different cases either or both of these causes may be operative. Of especial interest are cases of otitis interna acuta. Here little aid in diagnosis can be obtained from local examination, as the middle and external ears are usually found in a normal condition. In these cases it is generally impossible at first to make a positive diagnosis, and occasionally that cannot be made at all ante mortem. The genesis of this condition is still in doubt. Some claim that it is always to be considered as an extension from an acute cerebrospinal meningitis. Others hold that it is a circumscribed affection of the internal ear directly produced by infection from without. A case previously reported by the author (*Archiv für Kinderheilkunde*, Bd. XXVIII.), which upon autopsy showed only lesions in the labyrinth, demonstrates that it is possible for the disease to be entirely local in character.

French Journals.

Accidental Inoculation of Tuberculosis.—Jacob presents his observations made on a soldier with excellent family and personal history, upon whom the writer had operated for a large pocket filled with pus and fungosities in the iliac region. In his search for the portal of entry of the tubercle bacillus, Jacob discovered a small ulceration on the dorsal surface of the metacarpophalangeal articulation of the left middle finger. This ulceration had all of the characteristics of an anatomical tubercle resulting from the prick of a pin. The extirpation and examination of this lesion after animal inoculation, demonstrated clearly the origin of the tuberculosis. This accident happened two months before the development of the iliolumbar abscess.—*Lyon Médical*, February 16, 1902.

Chloroform in Cases of Cardiac Disease.—H. Huchard concludes that (1) Accidents due to chloroform are not more frequent, in the majority of cases, in patients suffering with heart disease or disease of the aorta than in patients affected with other affections. (2) Cardiac or aortic affections are not a contraindication to anæsthesia, upon condition that they are not infectious in the acute stage, and that the organism affected is not very feeble, and that the chronic affections have not reached the asystolic or dyspnœic period. (3) In those suffering with heart trouble or disease of the aorta, chloroform should be given in small quantities progressively and continuously, just to the point of almost total suppression of the palpebral reflex. (4) Generally speaking, the saying of Sédillot is applicable, that "Chloroform well prepared, and especially well administered, does not kill."—*Bulletin de l'Académie de Médecine*, February 11, 1902.

Traumatic Tabes Showing Itself First by Eight Spontaneous Fractures of the Leg and Foot; Cure of the Gastric Crises by Subarachnoid Lumbar Injections of Cocaine.—Abadie reports the case of a patient of forty-three years, who was attacked by tabes, the origin of which was unknown. There were no traces of infection, of intoxication or of syphilis, either hereditary or acquired. The first pain appeared after a violent traumatism, by which the pelvis and left hip were injured, causing a fracture of the neck of the femur with œdema of the whole leg. The apparent beginning of the tabes was ushered in by a series of eight spontaneous fractures of various bones of the leg and foot. All of these fractures were painless, and were cured after an immobilization of normal duration. These injuries had caused a curving of the bones of the leg, which proved an obstacle in walking. The posterior part of the bones was consolidated and extremely hard—a great contrast to the extreme fragility of the anterior surface of the same bones. Another feature was the occurrence of gastric crises during five months. These grew more frequent and intense, but they disappeared for three weeks immediately after a subarachnoid injection of cocaine. A second injection caused them to disappear entirely.—*Journal de Médecine de Bordeaux*, February 16, 1902.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 20, 1902.

Charles L Dana, M.D., Vice-President, in the Chair.

Symposium on Vaccination.—This was the special subject for the evening's discussion.

The Action Taken by the Health Department on Report of a Case of Smallpox.—Dr. Alonzo Blauvelt, Chief Inspector of the Division of Contagious Diseases of the Health Department, presented a communication on this subject. He said that whenever a case of smallpox was reported to the Health Department a diagnostician of the department was detailed at once to investigate the case, and the captain of the precinct was asked to have a police officer meet the diagnostician at the address given. An effort was made to ascertain the names and addresses of all who had been exposed to the disease, and a note was left for the disinfector regarding the number of rooms to be disinfected and just what was to be done. A policeman then accompanied the Health Department vaccinator to the place, and vaccination was offered to each one there. The schools attended by the children in the house were notified of the existence of smallpox at that address, and the children were not allowed to return to school for a period of three weeks. During this time the house was kept under surveillance, but, with the exception of the children, the occupants were allowed to go about their usual occupations. Patients ill with smallpox are removed to the department hospital without regard to the stage of the disease, but if a person had completely recovered he would not be taken away. A smallpox patient is taken to Riverside Hospital either in an ambulance or a coupé, according to the judgment of the diagnostician. A surgeon from the hospital accompanies the former but not the latter. The vehicle is disinfected with formaldehyde in a special room immediately after having been used, and before being sent out for another case. After having been kept under observation until certain of the diagnosis, the patient is taken to North Brother Island.

Dry Points Versus Glycerinated Virus from a Bacteriological Standpoint.—Dr. M. J. Rosenau, Director of the Hygienic Laboratory of the Marine Hospital Service, presented this paper. He said that human virus, although distinctly more potent in its protecting power, had been almost discarded because of the danger of the transmission of syphilis and other infections of tbe human family. In 1842 the use of bovine virus had been begun, but many years had elapsed before it became popular. In 1891 Copeland suggested that glycerin be mixed with the vaccine pulp as a sort of preservative. Glycerin could hardly be said to be a bactericide, because it kills bacteria only by a slow process of dehydration, requiring eleven days for streptococci and twenty days for diphtheria bacilli. In diluted form glycerin was well known to be a very favorable culture medium. While glycerin gradually dehydrates and destroys bacteria, it also gradually destroys the potency of the vaccine. The glycerin points do not keep their potency as long as dry points. Dr. Rosenau then described the bacteriological experiments that had been made with the glycerinated virus, and with glycerin suspensions from the dry points, the colonies being examined and counted on the third day. There were altogether ninety-two samples obtained in the open market, representing the products of eight different manufacturers. The forty-one dry points gave an average of 4,807 colonies per point, while the fifty-one samples of glycerinated virus gave an average of 2,865 colonies per point, an unnecessarily great contamination for glycerinated virus. Staphylococci, pus cocci, moulds indicating stable contamination, and other impurities were found. The glycerinated virus of some manufacturers was found to contain a great many more colonies than the dry points. Some of the tubes of glycerinated virus contained only a very minute portion of vaccine, while others contained a great deal of vaccine, a fact which might partly explain the figures obtained with this kind of vaccine. The glycerinated virus if placed on the market while "green" would be found to contain a large number of bacteria, while a few months later this same virus would contain a very much smaller number. The speaker said he believed that many of these impurities in glycerinated virus would not exist were it not that the manufacturers placed too much confidence on the preservative properties of glycerin. Pus cocci and staphylocci were found in both the dry and the glycerinated virus. Dr. Rosenau said that his opinion, based on the results of this investigation, was that government control should be exercised.

The Value of the Dry Point Compared with that of Glycerinated Vaccine Virus.—Dr. F. S. Fielder read a paper on this subject, based upon tests made since December 1, 1901. He said that glycerinated virus had now largely superseded the older virus on ivory points. Several lots of vaccine were prepared in different ways at the Health Department laboratory, viz., one lot of points was charged with the serum exuding after having curetted away the pulp for the glycerinated virus, and one lot was charged with the serum obtained after simply removing the top of the vesicle. No great difference was observed in these two lots, and what little there was seemed to be in favor of the points charged with the serum obtained after having removed the pulp for the glycerinated vaccine. The glycerinated virus from tweny-one consecutive calves and the ivory points from the same animals were tested and the results compared. Fourteen ivory points from eight private manufacturers were also tested. Of the twenty-one lots of glycerinated vaccine seventeen gave perfect results. Of 304 insertions with the dry points from the Health Department animals, ninety five were successful, or 25 per cent., while of the 137 insertions made with the dry points of private manufacture, eighty-three, or 60 per cent., were successful; in other words, the 571 insertions made with dry points from all sources gave 168 successful vaccinations, or 33.6 per cent. On the other hand, of the 315 insertions with the glycerinated virus, 296, or 92.9 per cent., were successful. The number of good-sized vesicles was decidedly in favor of the glycerinated virus. Four lots from one private firm gave the following results: Ten insertions with seven successes; nine insertions with four successes; nine insertions, all of which were successful, and ten insertions with seven successes. Another firm which charges points with the pulp from the bottom of the vesicle, furnished another series of points. The first lot of these gave eight insertions with eight successes, and two other lots also gave very good results, but a third lot, with which twenty-two insertions were made were all failures.

Constitutional Symptoms.—The cases were inspected from nine to eleven days after vaccination. Of the sixty-two cases vaccinated with Health Department ivory points, thirty-seven were successful, and none was severe. Of the forty-four cases vaccinated with the dry points of private manufacture, thirty-three were successful, one being severe, three marked, and twelve showing only moderate constitutional disturbance. Of the forty-one cases in which the glycerinated virus was used, in two the symptoms were severe, in six they were marked, and in fourteen were only moderate. The severer constitutional symptoms observed with the glycerinated virus the speaker thought could be partly explained by the fact that large vesicles occur in much larger proportion of the cases than where the dry points are used; moreover, these experiments had been carried out with what is called "green" virus.

Eruptions.—Of 282 cases vaccinated, nine, or 3.3 per cent., presented eruptions. Five of these cases occurred in children who had been vacinated only with ivory [illegible]. Most of the [illegible] were [illegible], one of [illegible] was of a [illegible] type and lasted only a few days. One was [illegible] an eruption [illegible] disease. The eruption [illegible] and the lesions very few. [illegible] the [illegible] typical symptoms of [illegible] the diagnosis of the [illegible] of the first case.

Rapidity of Healing.—Of [illegible] cases vaccinated with the ivory points prepared by the Health Department, [illegible] per cent. healed promptly, while of the cases vaccinated with the glycerinated virus [illegible] per cent. healed promptly. Of those which were slow in healing, [illegible] per cent. belonged to those done with the ivory points of the Health Department and [illegible] per cent. belonged to the cases vaccinated with the glycerinated virus. It seemed evident from this investigation that ivory points charged with the serum exuding from the vesicle were weak in vaccine. He could not explain why it was that the ivory points of the private firms gave so much better results than the ivory points prepared by the Health Department. He had had as yet no opportunity to test the actual time that ivory points retained potency, but some years ago he had studied this question with regard to the glycerinated virus of the Health Department, and had demonstrated that 100 per cent. of successes could be obtained with this virus after it had been kept for an average period of 7.7 months.

Tetanus and Vaccine Virus.—Dr. J. H. Huddleston was the author of this paper. He said that no proof had yet been adduced to show that tetanus had ever been inoculated with vaccine. While the calves used by the Health Department were old enough to have been fed on hay before coming to the laboratory, after their arrival they were fed on sterilized milk, so that after coming into the possession of the Health Department there was no danger of their becoming infected with tetanus through hay. It was well known that tetanus bacilli were found in horse manure, but it was not known whether this was so to the same extent with calf manure. He had examined the feces of twenty-five calves that had been fed on hay, and by inoculation experiments on animals had demonstrated that in only two instances was there infection with tetanus. His studies also pointed to the fact that calves were so little susceptible to tetanus that they would not present any symptoms of this disease even though the vaccine drawn from the animals were contaminated with tetanus bacilli. Experiments in the laboratory showed that glycerine exerted a distinctly inhibitory influence on the tetanus germs. Bone points and glycerinated virus might both carry tetanus, and experiments on animals were found not to be quite so delicate as cultural tests in establishing the presence of tetanus. It was found very difficult, however, to detect by cultural experiments the presence of a small contamination with tetanus because of the viscosity of the glycerinated virus. The author pointed out the possibility of contaminating vaccine with tetanus, and at the same time that it practically never occurs. His conclusions may be summarized as follows: (1) The feces of calves fed on hay may contain tetanus germs. (2) These germs do not develop with glycerinated virus. (3) Any form of vaccine virus—dry points or tubes of glycerinated virus—may be infected with tetanus, and may convey it, but no form of vaccine increases the amount. (4) Cultural tests for the presence of tetanus germs are somewhat more delicate than animal tests. (5) Inoculation by scarification is not a favorable method of inducing tetanus. (6) It is probable that the greatest precaution against the production of infected vaccine virus lies in the maximum of cleanliness observed in a vaccine laboratory.

Dr. Frank P. Foster said that he must confess at the outset that he was an opponent of glycerinated virus, though open to conviction. He had been delighted with the paper of Dr. Rosenau and the manner in which he had presented his results, which was in such marked and pleasing contrast with some of the literature of the day which presented results that [illegible]. Such [illegible] statements as that just quoted tended to make people nervous as to the use of vaccine. The [illegible] figures presented by Dr. Rosenau [illegible] that there is a good deal of glycerinated vaccine on the market which does not possess the characteristics supposed to belong to glycerinated virus. It was safe to say that the ivory points which Dr. [illegible] used were exceedingly poor, and the results reported by him with glycerinated virus were such as should be expected from good dry points. According to his own experience, the vaccine obtained from calves one or two months old was superior to that obtained from younger calves. Regarding the length of time that dry points retain their potency, he could say most positively that dry lymph would not deteriorate in seven or eight months if properly made and kept. Dry lymph would not deteriorate even at the temperature of the blood if kept absolutely dry. It was not enough for such lymph to be dried spontaneously; it must be desiccated. He did not know just what was meant by the term "pulp." Probably it was a whitish pulpy layer found beneath the epidermal portion of the pock. This he had always looked upon as consisting of the necrosed tips of the papillæ of the derma, arising from the fact that the form of pock in this instance was what had been described by Rindfleisch as "the diphtheritic pock." Of course, the latter term had no reference to true diphtheria. Dr. Foster said that he had always regarded this as an abnormal condition in the calf, and had invariably discarded it. If the term "pulp" included still living but softened tissue lying more deeply, there was no harm in using the lymph which exudes from that structure.

Dr. J. J. Kinyoun of the Marine Hospital Service said that about five years ago he had made some experiments at the Hygienic Laboratory in collecting lymph. He had found that the first part of it was quite rich in vaccinal material, and the last part comparatively weak. This might be because the lymph washes away some of the vaccinal organisms. If this were true, it would explain why points charged with the last part of the serum are unsatisfactory. The speaker said that he had been a consistent advocate of the superiority of the glycerinated virus over the dry points, and had been led to this belief because of his association with Dr. Copeland in 1891. Since that time he had had the privilege of inspecting most of the vaccine institutions of Europe and of the Orient, and he could say without hesitation that the superiority of the glycerinated lymph over the dry point could not be questioned. Quite recently he had inspected the vaccine institute of Japan. In that country smallpox hardly exists because of the systematic vaccination and revaccination of the people. The Japanese think no more of smallpox than of measles because the disease is so thoroughly under control. In the Philippine Islands it was found exceedingly difficult to preserve the glycerinated virus for any length of time; hence it became necessary to send it out immediately after its collection and preparation. There were very many sore arms there, and yet only 60 per cent. of primary vaccinations were successful. It was also said that the vaccinations were not as thoroughly protective as elsewhere.

Dr. Huddleston said that one cause of the remarkable differences in the number of bacteria found in the glycerinated virus was to be found in the fact that it was practically impossible to make a very homogeneous vaccine emulsion, and hence one portion would contain more vaccine particles, and perhaps more bacteria, than another portion. There must be some solid matter in all good vaccine, for if the serum be passed through a filter which would remove all solid matter, the filtrate would be found perfectly inert. The white pasty matter referred to by Dr. Foster was curetted out and used in the manufacture of the glycerinated virus. Both dry points and glycerinated lymph had been known to retain their potency for two years or more, but this was only a matter of general scientific interest, and did not indicate the practical life of the vaccine under ordinary conditions. The Health Department made use of 50 per cent. glycerine, *i. e.*, half glycerine and half water, in the manufacture of the glycerinated lymph. He felt that there was a decided difference in the character of the vaccine obtained for dry points from a cow and from a calf; the material from the older animal could hardly be curetted away so thoroughly and leave such a clean surface.

Clear Human Serum Effective.—Dr. A. Jacobi took issue with the statement that the clear serum is inactive, for, he said, clinical experience long ago had taught us that it was the clear serum which is especially to be relied on. Forty or fifty years ago the mode of vaccination in New York City was by taking a clear serum from a vesicle on the arm of a child that had been vaccinated eight days before. The physicians of those days were very particular to take only the clear serum, and they often had to make a number of visits before they struck just the right time for taking the vaccine. If this time were properly selected the vaccine would prove good to a certainty. Sometimes they were compelled to use the scab moistened with water, for, in those very early days even glycerin was not at hand.

Differences in Dry Points.—Dr. Rosenau said that after listening to the discussion he had come to the conclusion that confusion had arisen from the fact that all dry points are not made in the same way. Some manufacturers charge the points with a brush dipped in the serum exuding from the old cross-hatch scarifications; other manufacturers mixed the lymph with glycerin, and after keeping it some weeks, mixed it with normal blood serum and allowed it to dry on the bone points. There can be little doubt that vaccinia is an epithelial infection, and that the glycerinated pulp by taking away vaccinal elements showed that the epithelial layer contained the maximum of the bodies.

Dr. Huddleston said that he had seen in London vaccinations made in exactly the way described by Dr. Jacobi. The vaccinations were made with a fluid or serum which looked perfectly clear, but this seemingly clear fluid still contained very minute particles, and if they were removed by filtration the filtrate would be found to be inert.

NEW YORK ACADEMY OF MEDICINE.

Section on Medicine.

Stated Meeting, Held February 18, 1902.

E. Franklin Smith, M.D., Chairman.

A Consideration of Some Points in Regard to the Etiology and Diagnosis of Endo- and Pericarditis.—Dr. Frederick A. Packard of Philadelphia read this paper. He said that the heart acts well when acting naturally and in proper regulation to the vascular system. This organ was frequently looked upon as a pump, and the rest of the vascular system as merely an arrangement of tubes connected with this pump, but such a narrow view was apt to lead to mistakes in therapeutics. The heart should not be too much considered to the exclusion of the rest of the vascular system. Even in the heart itself mural endocarditis could reach a high grade without serious consequences, whereas a much less extensive endocarditis of the aortic valves would lead to much graver results. From an anatomical standpoint, the lining membrane of the heart was of greater importance than that of the rest of the vascular system. Any inflammatory process occurring in the body in a part which could not rest was apt to become chronic. The exact agent producing endocarditis was not always demonstrable even at the present time. He believed that degenerative changes in the valves and their endothelial coverings were too frequently spoken of as endocarditis. If in fatal cases of active endocarditis microorganisms were found, corresponding to the bacterium causing the primary infection, it was reasonable to assume that cases of endocarditis not terminating fatally had a similar origin. Too much weight should not be attached to the absence of microorganisms in lesions produced by a former endocarditis. The term, chronic valvulitis, it seemed to him, was too often applied to what should be looked upon as the results of a valvulitis.

Referring to pericarditis, the speaker said that in 1899 the interesting suggestion had been made that the pericardium served as a protective covering for the heart, preventing its overdistention as does the leather covering of a foot-ball. Delirium had occurred so frequently in his experience with pericarditis that he made it a rule when this symptom was present to carefully examine the pericardium. No very satisfactory explanation of this delirium had been offered. While it was comparatively easy to make the diagnosis of pericarditis when the latter developed under observation, it was another matter when the case was first seen after the friction sound had disappeared, owing to the increase of the effusion in the pericardial sac. Little reliance could be placed upon the apparent displacement of the apex beat. It was not unusual to find a double apex beat, one in the fifth intercostal space near the nipple, and another in the third or fourth intercostal space close to the sternum. The cone-shaped area of cardiac dulness, usually said to be characteristic of pericarditis, could hardly be said to be diagnostic. Extension of the cardiac area to the right could not be relied on because in fatty degeneration of the the heart, owing to the dilatation of the auricle, the cardiac area often extended considerably to the right of the sternum. In the vast majority of cases of pericarditis a valuable sign was dulness in the fifth intercostal space to the right of the sternum. The occurrence of dulness beneath the manubrium of the sternum had been claimed to be a useful indication of pericarditis, and experiment on the cadaver had shown that whereas the injection into the pericardial sac of 150 c.c. of fluid would cause dulness in this prolongation of the pericardium over the great vessels, increase in the area of dulness at the base was not noted until 250 c.c. had been injected.

The Pathology and Treatment of Endo- and Pericarditis.—Dr. William H. Porter presented this paper. He said that a common appearance at the necropsy on a case of pericarditis was the "milk patch," a white glistening appearance of the pericardium due to the formation of new connective tissue in or underneath the pericardium. By some these were looked upon as the results of a previous inflammatory action; by others as a disturbance in the nutritive activity, and in no way connected with an inflammatory process. The speaker thought the latter was probably the correct explanation. Occasionally, a large hemorrhage was met with, non-inflammatory in origin, due to rupture of one of the large vessels. Of the non-inflammatory lesions there was the occasional involvement of the pericardium by new growths, such as sarcomata and gummata. Tubercular involvement of the pericardium was generally considered to be an inflammatory process. In the early stage of a simple acute pericarditis there would be found simply a congestion of the membrane, most marked around the great vessels. The inflammation usually results in a more or less abundant exudation of the constituents of the blood into the pericardial sac. In the non-suppurative type, under favorable circumstances, the fluid would be gradually absorbed. Most commonly certain bands of adhesions formed, and these might become so numerous as to almost obliterate the cavity of the pericardium. In endocarditis the membrane became congested, and subsequently there was usually more or less cell formation. Vegetations may tions in the endocardium, owing to the changes of nutritive activity, might undergo degeneration and be washed away in the current of blood, thus giving rise to emboli of distant parts. The simple acute endocardial inflammations were very commonly rheumatic in origin, as in the case of the malignant form. The main thing in the preventive treatment was the thorough and hygienic management of diseases likely to result in such inflammation. The diet should be highly nutritious and most digestible, and the hygiene should be of the best. The treatment of the acute inflammation of the endocardium or pericardium should comprise absolute rest. Locally, for the relief of the pain and tachycardia, heat or cold applied directly over the precordial region would give prompt relief. The question of tapping the pericardium was an interesting one, but there was a great diversity of opinion on this point. If the quantity of the effusion were so great as to seriously embarrass the heart's action, the imperative indication would seem to be the removal of the fluid by tapping.

Dr. S. S. Burt agreed with Dr. Packard that many of the cases of so-called valvulitis were in fact only the scars of an old inflammatory process which had long since come to an end. It was for this reason that he had long maintained that some of these cardiac cases were really good life insurance risks. There were many cases of pericarditis in which it was difficult to make the diagnosis. He had heard the friction sound in some cases in which there was a good deal of fluid present in the sac. The great point in the treatment was absolute rest, and as for drugs an experience of twenty-five years made him positive that digitalis does more good than any other one drug in disease of the heart.

Dr. Lewis A. Conner said, concerning the diagnosis of pericarditis with effusion, that it was one of the most difficult things in the whole realm of cardiac diagnosis. Sometimes every sign seemed to fail. He recalled one case in which the dulness to the right of the fifth intercostal space had failed him as a sign of pericarditis. He had at present under his care a case of pericarditis with effusion in which the inequality of the pupils was peculiarly well marked.

Dr. Alexander Lambert said that the fact that malignant endocarditis might occur without the presence of any germs had been forcibly impressed upon him last winter. In this case both aerobic and anaerobic cultures were made from the blood on five different occasions, and they remained absolutely sterile, yet at the autopsy there was abundant evidence of the existence of malignant endocarditis. He had found a helpful diagnostic sign in pericarditis to be the alteration in the level of the fluid in the pericardial sac on causing the patient to lean forward.

Dr. Charles E. Quimby said that many years ago a German book on physiology had given him a new insight into the action of the mitral valve. According to this description the mitral valve is not a valve in the ordinary acceptation of that term, but, being held with its tips down, the action of the columnæ carnæ was to drive the valve deeply down into the apex of the heart. This valve then acted as a tent-shaped plunger, and in doing so left the ventricle filled with blood at the end of systole, the blood from the auricle being held in the valve as in a cup. He felt that every case exhibiting a persistent high arterial tension should be put down as a possible case of endocarditis, and should be treated prophylactically in accordance with this view.

Dr. James J. Walsh said with regard to the possible implication of the recurrent laryngeal nerve, that some cases of supposed very late development of hydrophobia were, in reality, examples of death from pericarditis. As to the detection of pericardial effusion, he would recall the fact that in one of the Vienna hospitals it was the custom to examine the patients in the knee-chest position, and with the patient in this posture it was possible to make out certain small effusions which could not be detected by other means.

Pneumonia in the Light of Modern Research.—Dr. Stephen S. Burt was the author of this paper. (Vide page 368.)

Disinfection of Pneumonic Sputa.—Dr. W. Gilman Thompson said that a large number of observations had borne out the statement that pneumonia is becoming more prevalent. Thus, in an edition of Watson's "Practice of Medicine," published thirty years ago, that author, despite his enormous clinical experience, makes the astounding statement that he saw only five or six cases of idiopathic pneumonia each year. The precautions laid down in the paper were interesting, but he doubted, even if they could all be carried out, if they would accomplish much in the way of staying the march of the disease. For example, the diplococcus of pneumonia was known to be ubiquitous, hence, as it was frequently present in the mouth, what difference would it make if there were a few more or a few less? We did not know what made some of these organisms virulent while others were not. He did, however, firmly believe in the importance of disinfecting the sputa, a point which was very commonly overlooked by physicians. He had met with two or more epidemics of pneumonia in hospital practice and had promptly checked them by isolating all of the pneumonia patients, emptying the ward and disinfecting it.

Contagiousness of Pneumonia.—Dr. Beverley Robinson said that he had been interested in the measures suggested by Dr. Burt for the prevention of pneumonia. No doubt our city would be healthier, now that the streets were to be kept cleaner, but people would still continue to go to the theatres and to other crowded and badly ventilated places, such as the New York Academy of Medicine, and hence we must not look for brilliant results immediately from such efforts at prophylaxis. About fourteen years ago Dr. Henry F. Walker read a paper before the Practitioners' Society of New York city, in which he pointed out the apparent contagiousness of pneumonia. This had greatly impressed the speaker at the time, and he was personally disposed to believe that not only pneumonia, but even ordinary colds, were, to a certain indefinite and unknown extent, contagious.

Creosote Treatment of Pneumonia.—Dr. Robinson said that four years ago he also read a paper on this subject, and had expressed the belief that by the use of inhalations of pure creosote the pneumonia patient could be benefited and the attendants protected. At the present time he was not prepared to admit that creosotal possessed any advantages over creosote, nor could we legitimately hope that any medicine given internally could be expected to successfully combat toxæmia of the nature of pneumonia. He was in thorough accord with Dr. Charles E. Nammack, who, in a paper published a few days ago, stated that his main reliance was on the proper use of four things, viz., strychnine, nitroglycerine, oxygen, and alcohol. Of course, the creosote inhalations should be begun very early in the disease. He was working at present with a view to finding some means by which the heart's action could be kept up for twenty-four hours or more in the critical periods of a pneumonia, and if he succeeded in finding this great desideratum, he would take pleasure in imparting the information to the profession.

Dr. Andrew H. Smith said that the different decades of life present different mortality rates from pneumonia. It was well known how much more dangerous pneumonia was, for example, in a person with impaired kidneys, and also that as life advances there is greater liability to such impairment of the kidneys, hence the increasing gravity of pneumonia late in life. The micrococcus of pneumonia was peculiar in the great variations in virulence which it displays. It seemed to be established that a mucous surface, *i. e.*, ciliated epithelium, does not afford a favorable nidus for the propagation of the pneumococcus; on the other hand, this organism would grow readily on a serous surface. When, for any reason, the pneumococcus was carried down into the air cells, it would find a congenial soil for its growth. Even then, if the person's vitality was good, it was probable that no harm would result, but if the vitality were lowered, pneumonia would develop. His own opinion was that from the moment an active, propagating pneumococcus is present in an air cell in the lung the person has pneumonia. As a result of the growth of the pneumococcus, toxins are developed and are absorbed, and from these arise the well-known phenomena of pneumonia. So long as the process of consolidation extended, just so long would toxins continue to be formed. He was strongly of the opinion that it was possible to so act upon the whole mass of blood that the air cells in the lungs could be made an unfavorable nidus for the propagation of the pneumococci. The beechwood creosote would probably do this, while creosotal should accomplish the same result with more comfort to the patient. By such treatment the disease would be so altered that defervescence would take place in about 90 per cent. of the cases by lysis instead of, in a similar percentage, by crisis. This was a very significant fact. Mention had been made of the use of nitroglycerine, and this always pleased him. Whenever a pneumonia patient appeared cyanosed, nitroglycerine should be given rather than digitalis.

Dr. F. A. PACKARD said that he had felt for a long time that we were making a mistake in placing pneumonia among the constitutional diseases. One of our greatest functions was prevention. Pneumonia was primarily an infection of the lung, and if we were to prevent it we must look upon it as a constitutional disease with a local manifestation.

Dr. ALEXANDER LAMBERT said that the recent epidemic of pneumonia in the school at Groton, Mass., was merely an epidemic among a number of school-boys who had been careless in their out-door sports during a spell of changeable and inclement weather. These cases had nothing peculiar about them; they were frank cases of ordinary pneumonia. He could not agree with Dr. Packard about pneumonia being a constitutional disease with a local manifestation. He had made bacteriological experiments on upwards of 200 cultures, but had learned that the pneumococcus is not usually found in the blood until shortly before death. The disease was apparently a local inflammation in the great majority of cases, and eventually became a septicæmia.

Dr. MORRIS MANGES said that the reason the pneumococcus was not found in the blood of pneumonia patients earlier was that too small a quantity of blood was taken for the examination. The prevalence of influenza would explain not only the increased frequency, but the higher mortality from pneumonia in the last decade. According to his experience, pneumonia was much less fatal in hospital than in private practice, and hence one should be slow to accept the statement that pneumonia is more dangerous among the poor. Coolidge had taken the statistics of the Massachusetts General Hospital for ninety years, and had shown that there had been practically no change in the disease. He would like to know whether Paris, with its clean streets, had less pneumonia than other cities not kept so scrupulously clean.

Dr. S. A. KNOPF said the method of collecting ashes in our city was certainly calculated to injuriously affect any one suffering from disease of the respiratory organs. Spitting in the streets was a nuisance, but people must spit; hence they should be provided with pocket flasks for that purpose, and the municipality should furnish public spittoons and keep them properly flushed out.

Dr. BURT, in closing the discussion, asserted positively that pneumonia was remarkably prevalent, and that many of the milder cases passed entirely unrecognized. He was not yet satisfied that pneumonia begins in an air cell and spreads from there throughout the body. He had seen patients walking around with one lung completely consolidated by a pneumonic process, and he had even seen persons with double pneumonia who were not apparently very ill. Others, again, with only a small area of consolidation, became extremely ill, and even succumbed to the disease. Dr. Manges was right in the statement that if the pneumococci were not found in the blood during the course of the disease, it was because of a faulty technique.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, Held February 17, 1902.

PARKER SYMS, M.D., PRESIDENT.

Lever Axis Traction Forceps.—Dr. REUBEN CRONSON presented an instrument of this kind which he had devised, and which he claimed would compel the fœtal head to travel in the axis of the pelvis. It consists of two long curved levers, an anterior and a posterior one. The former fixes the head against the posterior plane of the pelvis, and the latter is used to make traction downward in the axis of the pelvis. The pelvis curve of the instrument is the result of observations on the cadaver.

Symposium on Obstetrics.—This was the special order for the evening.

Management of Normal Labor.—Dr. BERNARD COHEN of Buffalo read the opening paper in this symposium, taking the above for his theme. He said that, aside from the introduction of aseptic practice, nothing, perhaps, had done so much towards reducing the morbidity of the puerperal woman as medical supervision during pregnancy. Physicians should educate their patients to the necessity of such supervision. The urine should be examined once a month up to the eighth month, and then every week, the examination including not only the testing for albumin, but a quantitative determination of urea and indican. If the daily quantity of urea fell below 300 grains, the patient should be watched closely, and appropriate treatment instituted to avert the possible attack of eclampsia. The physician should inquire minutely into the diet and the general habits of life of the pregnant woman; should see that a proper nurse is engaged, and that a suitable room is selected for the confinement. The patient should also be examined from time to time. At the time of labor, before making the usual examination, the physician should be most careful to scrub the hands with a brush and green soap, and afterwards immerse them in a 2-per cent. solution of lysol. The finger should be introduced carefully under the guidance of the eye, the labia being separated first. The instruments should not only be made sterile, but should be so placed as to be kept sterile. He was in favor of using an anæsthetic in moderation during labor, and believed it did no harm. Aside from holding back the head and aiding slow distention of the perineum, it was often of decided advantage to apply to the perineum cloths wrung out of hot water until the perineum was sufficiently thinned and softened. Attention was directed to the necessity of quickly cleansing the eyes of the newlyborn infant, and to the importance of keeping the hand on the fundus uteri for an hour after delivery in order to secure good uterine contraction and prevent the accumulation of blood clots in the uterine cavity. The patient should be kept in bed for twelve days; she should not be allowed to go about the house until the third week, and should not resume her work until the sixth week.

Use and Abuse of the Forceps.—Dr. EDWARD A. AYERS, in discussing this subject, expressed the opinion that the forceps were more often applied too soon than too late. About one case in every twenty or twenty-five was benefited by the proper use of the forceps. Their application presupposed a knowledge of the presentation and position, a fairly accurate estimate of the relative size of the head of the fœtus to the birth canal and of the amount of available uterine power. An almost unexceptional indication for the application of the forceps was a slowing and weakening of the uterine contractions, as was also a rise of the [illegible] The first object with the forceps should not be to bring down the head, but to assist its passage through the pelvis. The traction should not last longer than the uterine contractions, and the blades of the instrument should be relaxed at the end of each traction. The forceps should be applied if possible in such a way that one blade lay over the posterior parietal eminence, and the other over the anterior malar bone. With the ordinary forceps it was possible to make proper use of the traction in the axis of the inlet, but in a difficult forceps case in which the head was not engaged, the speaker's experience was limited, and hence he favored the use of the Tarnier axis-traction forceps in such cases. The forceps should almost always be removed before the delivery of the head, and the patient's knees should always be extended at the time the head reached the vulva, because it was easy to show that the flexed thighs increase the pressure on the outer portions of the perineum.

Diagnosis and Treatment of Puerperal Sepsis.—Dr. Frederick Holme Wiggin read the paper. He said that while our knowledge that wound infection is the essential thing in puerperal fever had led to great improvement in the statistics of lying-in institutions, it was strange that wound infection in the ordinary daily obstetric practice of physicians was almost as frequent and was followed by almost as high a rate of mortality as fifty years ago. When the pulse of the puerperal woman rose above 100 and the temperature above 100.5° F. and remained so for twenty-four hours, it should call for a most searching examination to ascertain its cause. When septic endometritis passed beyond the uterus there would be chills and daily variations of temperature, and a bacteriological examination of the secretions would probably show the presence of staphylococci. The presence of general peritonitis might be the first to attract attention to septic infection if the physician were not constantly on the alert. It usually made its appearance between the third and seventh day. Phlegmasia dolens ordinarily developed in the second week. Malarial infection could be excluded by an examination of the blood for the malarial plasmodium, and typhoid fever could be ruled out by an examination for the Widal reaction. The treatment of puerperal sepsis should be preventive, and should consist in the aseptic conduct of the labor and of the puerperium. From this it was obvious that not only should the physician be careful about the sterilization of his hands and instruments, but the nurse should be competent to keep herself, the patient and the latter's surroundings surgically clean. A rise of temperature should lead to an inspection of the genitalia, and, if necessary, the uterine cavity should be explored and treated in accordance with the indications. Prompt and vigorous local treatment at this time should be sufficient to check the septic process. The speaker recommended thoroughly emptying the uterus, cleansing with hydrozone, and applying Monsell's solution. If pyæmic conditions were recognized before the onset of pneumonia, the patient might be saved by prompt cleansing treatment and the performance of abdominal section. In advanced puerperal sepsis little help could be expected from drugs; our main reliance should be on frequent and copious hot saline infusions and on a generous diet.

Venesection and Transfusion in Puerperal Eclampsia.—Dr. ROBERT ABRAHAMS said that his attention had been first directed to this subject by a case of eclampsia in which the very grave condition of the patient had improved suddenly, and almost as if by magic, by the occurrence at this critical moment of a profuse post-partum hemorrhage. Since then he had made use of this knowledge by resorting to venesection followed by saline infusion in the bowel. His usual practice in these cases was to remove, by venesection, eighteen to twenty ounces of blood, and then inject high up into the colon about three quarts of hot saline solution. Four cases were narrated to prove the effectiveness of this mode of treatment. Venesection, he said, improved the pulse, induced free [illegible] and by causing thirst, led the patient to drink freely, thus still further assisting the eliminations. In addition to this, the venesection removed considerable toxic material from the system and relieved the congestion of the brain. Venesection alone had been employed in puerperal eclampsia from time immemorial, but the use of the combination of venesection and saline infusion was of comparatively recent date. In view of our present knowledge, there seemed to be very few contraindications to this treatment. When the patient was on the verge of collapse, it was probably better to inject the saline solution into the vein.

Dr. RALPH WALDO said that when cases of puerperal sepsis were admitted to his hospital service, the first step taken was to examine the parts thoroughly. If the os were open, whether there was a foul discharge from it or not, the presumption was that there was something in the uterus which should be removed. The uterus was accordingly explored, usually without an anesthetic, and then carefully curetted, but not with a sharp curette. The uterus was then well washed out. If abscesses formed they were opened and washed out with peroxide of hydrogen and afterwards with sterile water, and then the cavity packed. He had never seen a case of puerperal sepsis in which he was obliged to do hysterectomy.

Dr. WILLIAM R. PRYOR said that the greater the degree of sepsis the less he believed was the indication for hysterectomy. He believed that most of Dr. Vineberg's cases were examples of the remote and not the true immediate results of puerperal septicæmia. Curettage of the septic uterus carried with it a mortality of about 24 per cent.; curettage of the putrid uterus, containing less virulent germs than the streptococcus, was a very different matter. His method of treatment was the isolation of the infected uterus, by packing 5 per cent. iodoform gauze into the pelvis, the uterus having been first curetted. This treatment gave rise to a degree of iodism which would be dangerous were the treatment not associated with saline infusion. This treatment had been carried out in a large number of cases of puerperal infection occurring after the fourth or fifth month of pregnancy, and with no fatalities. Cases occurring in the earlier months belonged to a different category.

Dr. GEORGE TUCKER HARRISON said that it was wrong for this discussion to go on without referring with gratitude to the monumental work of Semmelweiss, a man to whom the medical profession owed a vast deal. This investigator's views were essentially those heard expressed at this time, and his name should not be mentioned without a feeling of reverence. It could not be denied that our means of treating cases of severe puerperal sepsis were still very limited and unsatisfactory. The cases referred to by Dr. Waldo were nothing more than cases of sapræmia; they would get well, as a rule, even without any treatment. In cases of streptococcus infection the fever would usually begin on the second day, and such cases almost invariably terminated fatally.

Dr. S. MARX said that in cases presenting high temperature, a low pulse, and a stinking discharge—cases of sapræmia—were the ones in which there was a distinct indication for the curette. It was the height of folly to use either a blunt or a sharp curette in a uterus in which there was no material to be removed. His former experience with Marmorek's antistreptococcus serum had been uniformly bad, but recently he had made use of fresh serum, prepared in this country, and had been pleased with the results. Occasionally heroic doses of this serum—up to 20 c.c. every three or four hours—would save the patient. He had been deeply interested in the practical and timely paper presented by Dr. Abrahams. He had occasionally employed venesection in cases of puerperal eclampsia up to the point of producing acute anæmia, and had followed this by saline infusion. In the cases in which he felt that bleeding was indicated, the indication seemed to him to be to empty the uterus immediately, and his own preference was for evacuation of the contents of this organ and allowing bleeding to take place from it. In some of these cases it seemed justifiable to consider Cæsarian section. He had employed veratrum viride because it was a medical method of bleeding the patient, but he was compelled to say that he had seen some exceedingly severe convulsions occur while the patient was under the influence of this drug and the pulse down to 60.

Dr. L. Zwisohn emphasized the importance of accurate diagnosis. This was easy where marked symptoms appeared on the third or fourth day, but in those developing later, and more insiduously, there was a chance for error even with careful physicians. He would direct attention to the symptom that he considered of great diagnostic value—*i. e.*, a peculiar luster of the eye.

Dr. Alexander Lambert said that it had been recently shown that the substance which Buchner called alexin is a composite body, made up of substances formed in widely distant parts of the system. An animal might be immunized as highly as possible, and only one of these bodies would be increased—the immune body. A bactericidal serum would not act unless there was a sufficient amount of alexin present in the body. No method was known at present by which the alexins could be increased. Immunization does not do it—in fact, it sometimes seemed to diminish it. Until this gap in our knowledge were bridged over we must be groping in the dark with our bactericidal sera.

Dr. A. Ernest Gallant said that the most important observation made by Semmelweiss was that if we left our obstetric patients alone they would do much better, and would be free from fever. Since his time the most important thing we had learned was that we could examine patients if we were careful to sterilize our hands. After all, the great thing was not the particular antiseptic employed, but to "scrub, scrub, scrub." The speaker closed his remarks by reciting a humorous paraphrase of a familiar rhyme by Mark Twain, intended to emphasize this point.

Low Fees Partly Responsible for Puerperal Sepsis.—Dr. B. Cohen said that he believed there would be much less puerperal sepsis if obstetricians were properly paid for their services. He believed that the average fee for an obstetric case in this country was less than ten dollars. Many physicians would attend cases of scarlet fever, measles and various septic cases, and would then go to the lying-in room. We should allow at least twenty-four hours for a case of normal labor. He was in favor of placing the axis traction forceps more in the hands of the general practitioner, though admitting that in very expert hands the ordinary classic forceps could be made to do almost as much as the axis traction forceps.

Dr. E. A. Ayers said that in operative work of general surgery the operation extended over a comparatively short time, whereas in puerperal cases the time of exposure to conditions favorable to septic infection was many times greater. This he took to be one of the great causes of puerperal sepsis. In the treatment of eclampsia there could be no routine method. These patients die either from the coma or from heart failure. He was in favor of using anticonvulsive remedies, and at the same time hastening the processes of elimination. If by such treatment one could gain on the convulsions, it was much better not to immediately empty the uterus, as this procedure in itself was an irritant, and was almost sure to precipitate another convulsive attack. He wished to condemn the common practice of using chloroform in these cases just at the time when the patient most needs oxygen. There was a class of cases in which venesection was useful, *i. e.*, those in which the brain is being overwhelmed by the terrific intracranial pressure. In such cases Dr. Abrahams' treatment was admirable, but it was not applicable to all cases of puerperal eclampsia by any means.

Dr. Wiggin said that he had found that where abscesses, the result of puerperal sepsis, were simply opened and drained through the vagina, it often became necessary to do a subsequent operation. For this reason he had come to look upon hysterectomy in these cases as being a preferable plan. After studying the treatment advocated by Dr. Pryor he felt that it did not have a rational basis. It was well known that iodine has no action on bacilli, but upon their products, and hence the surcharging of the system with iodine seemed to him rather detrimental than otherwise. The only benefit to be derived from opening the cul-de-sac and packing in gauze was the formation of adhesions. The chief difficulty in the treatment of puerperal sepsis was the rapidity of the process.

New Instruments.

SOME MODIFICATIONS OF THE EARLIER PERIMETER OF DR. SKEEL.

By HERBERT WRIGHT WOOTTON, M.D.,
NEW YORK.
ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL, AND OPHTHALMOLOGIST TO THE GERMAN POLIKLINIK.

The self-registering apparatus, devised by Dr. Skeel and attached to the perimeter which bears his name, is undoubtedly of the greatest service in the examination of the field of vision, enabling the observer to record his findings with accuracy and rapidity, during this somewhat tedious procedure. The writer has attempted, by a few simple modifications, to extend the sphere of usefulness of this perimeter, in such a manner as to make it applicable to the angular measurement of strabismus and to the determination and registration of the monocular fields of fixation. The efforts of Mr. E. B. Meyrowitz in these directions have given the writer great satisfaction.

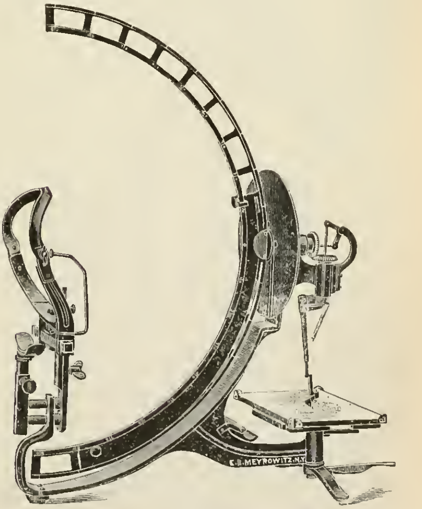

Fig. 1.

Whether we believe that advancements or tenotomies should form our primary operations in cases of concomitant strabismus, it is certainly advisable that we should know the exact degree of deviation before operating, for our opinion of the result and the deductions which we draw therefrom cannot but be materially influenced by the degree of squint which was present. The terms "a slight amount" or "an extreme degree" are hardly expressions upon which we can rely for future guidance. The most accurate means of measuring the degree of strabisment is by the Landolt method, which at the same time is so easy and so rapid that there would seem to be no good reason for repeating it by any other. The circular disc placed at the center of the arc of Dr. Skeel's perimeter, while forming an excellent and necessary background in the examination of the field of vision, renders the determination of the angle of strabismus impossible, and the writer has therefore caused it to be so constructed that it can

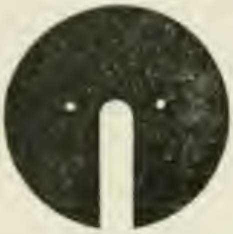

Fig. 2.

be readily removed and replaced. With the disc removed the observer proceeds to estimate the angular deviation in the usual way. The head being fixed by the headrest to be presently described the squinting eye is placed in the center of the arc, and the fixing eye is directed to a candle flame, twenty feet distant. One has now only to move a small taper along the arc, until its reflection shall coincide with the center of the pupil of the deviating eye, to read off from the scale the apparent degree of angular deviation. This apparent deviation is estimated by the pupillary axis, and, if the squinting eye be quite amblyopic, the apparent deviation is all that it is necessary to determine, for in such cases there will be no visual line, but in cases in which the squinting eye possesses good or fair vision the angle formed by the visual line and pupillary axis, designated the angle kappa by Landolt, frequently is sufficiently large to become of some importance in our calculations. It should be estimated by the easy and rapid method which Landolt suggests. The head remaining fixed as before and the disc being removed, a small taper is placed at the central point of the arc, and the patient is told to fix it with the squinting eye, his other being covered. The observer now closes one eye and with the other, placed directly behind the taper, notices whether or not the reflection of the taper coincides exactly with the center of the patient's pupil. If so, there is no angle kappa, and the apparent deviation is also the true one. Most frequently, however, this is not the case, and the reflection will then fall either to the outer or to the inner side of the pupillary center. If to the inner side the angle kappa is said to be positive, if to the outer side negative. In either case the taper is held in place and, the patient maintaining fixation, the observer moves his own eye outward if the angle be positive, inward if it be negative, along the perimeter's arc until the reflection from his new point of observation corresponds exactly with the center of the patient's pupil. One-half this distance expressed in degrees of the perimetric arc denotes with sufficient exactness the angle kappa of the eye examined. When positive the angle kappa should be subtracted from the apparent deviation in divergent cases and added in those that are convergent. When negative, we should add it when the squint is divergent, and subtract it when the squint is convergent. A dilated pupil facilitates this examination. The writer is in the habit of measuring the degree of strabismus both before and after the employment of atropine, reserving the estimation of the angle kappa for the latter examination.

In the determination of the monocular fields of fixation it is absolutely necessary that the patient's head should be immovable, and even when taking the field of vision some means of fixing the head is desirable when we wish to be particularly accurate. The rest shown in figure 3 answers this purpose very well. It is adjustable for either eye and can be raised or lowered to suit requirements. Rotation on the vertical axis is prevented by fixation by means of the teeth, and this point of fixation, as well as the chin rest below it, is capable of vertical adjustment. Rotation forward on the horizontal axis is limited by the iron arch, which is bisected somewhat above the middle line, in order to accommodate its form to differently-shaped foreheads. By means of the thumb screws the two segments can be clamped at the angle desired, after the patient's head has been brought into the vertical position. During the examination the patient should keep his forehead constantly in contact with the upper segment of the arch. The angular rod with a bulbous extremity, shown in figure 1, slightly in advance of the head rest, enables the observer to bring the eye of the patient to the correct level and, when this has been done, the rod can then be turned downwards and to one side, and does not interfere with subsequent procedures. In cases possessing fair vision, the best test object to employ in taking the fixation field consists of two small black squares upon a white background, the "double dot" of Duane. Should the eye be extremely amblyoptic or the patient under atropine, a small lighted taper should be substituted. The patient's head being fixed by the head rest the field of each eye is taken separately, the eye not under examination being covered, preferably by a bandage. The test object is moved along the different meridians from the center to the periphery, the patient being told to follow it with his eye and to exert his utmost power in so doing. When the eye has reached its extreme limit of rotation in the meridian under examination the two squares will seem to the patient to run together, and the observer can check the patient's statements by noticing the behavior of the eye, which will cease to follow the test object at the point of extreme rotation. When a taper is used, its reflection will be seen to move and the eye to remain stationary when the limit of rotation has been reached. In the examination of the lower part of the field the upper eyelid should be elevated by the finger of the observer. To record these results the writer has constructed the chart shown, reduced about one-half, in figure 4. It is drawn to suit the scale of Dr. Skeel's self-registering apparatus. The scheme of the meridians is that employed by Landolt, and is the one that has been

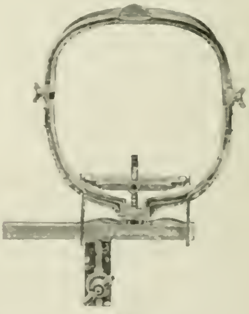

Fig. 3.

found most serviceable. The fields of fixation shown in black are those of the writer, who does not suffer from any muscular anomaly. It will be noticed at once that their downward and outward limits are somewhat more remote than the average tropometric findings. The writer thinks that the fields of fixation, as found by the perimeter, are very generally somewhat larger than when the tropometer is used. Possibly the reason for this is that the test object, by forming a continuous point of fixation for the eye, renders it easier for the patient to maintain an extreme degree of rotation. Be this as it may, fields of fixation vary greatly in different normal subjects, and those shown on the chart are intended merely as a guide, it having been thought better to exhibit one normal field for this purpose, than to depict one constructed from a table of averages. He who takes the field of fixation should be aware of its possible normal variations, and in any case its value is comparative.

As a guide to operative procedure in latent muscular anomalies, it is not the purpose of this paper to discuss the value of the fixation field, but in cases of concomitant strabismus, particularly when convergent, the writer considers its determination as a matter of the greatest importance. In these cases a bilateral restriction of the external rotations, when the squint is manifest both for distance and near, is a very sure indication of the existence of a secondary insufficiency of divergence. It is when this condition is present that advancement of both externi, without tenotomy of the interni, produces the happiest results, and, when the external rotations are reduced to thirty-five or forty degrees, we may attempt this procedure with the greatest assurance. The determination of the fields of fixation is also of inestimable value in paretic conditions, particularly when the muscles of both eyes are involved, in which case it is difficult and, at times, impossible to arrive at a correct diagnosis by means of the diplopia alone. The charts afford the observer an excellent means of keeping his records, and frequently illustrate in a beautiful manner the limitations of muscular action in the parts of the field dominated by the paretic muscles.

London's Parks.—London has fifty-six parks and gardens of from one-fourth of an acre to 198 acres, and thirty open spaces and commons from one to 267 acres in size.

CERVIX CLAMP FORCEPS.

By Z. ORTO, M.D.,
PINE BLUFF, ARK.

All instruments are supposed to aid the surgeon in doing his work with neatness and dispatch, and those that combine the above with hæmostatics are to be recommended. The writer recently conceived the idea of the clamp forceps figured in this article, and, with the aid of Messrs. Tieman & Co., the instrument is presented to the profession. As will be seen, the instruments are to be used in pairs, in repairing the lacerated cervix; and, when properly used, the time is greatly reduced, and the operation is practically bloodless. By their use, the author has been enabled to do Emmet's operation in eleven minutes.

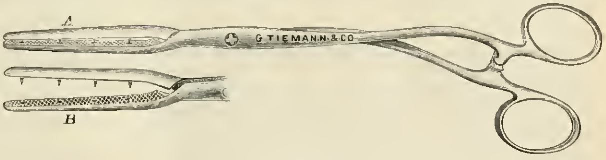

Fig. 1.

The patient should be in the dorsal exaggerated lithotomy position, and a perineal retraction used. Edebohls' speculum is used by the author, and serves a good purpose. After full dilatation of the cervix, the clamps should be passed as seen in Figure 2, clamping them loosely at first. The dotted lines show the lines of incision. These incisions are to be made with a sharp-pointed, curved bistoury, by transfixing the tissues at the apex of the triangle, and with one sweep of the knife on each side the cutting is completed. The clamps are now tightened and turned in such manner as will roll the incised edges outward—from each other—using the clamps *in situ* for counter pressure in stitching, after which they are removed. The sutures should be tied loosely, as there is always some compression of the tissues.

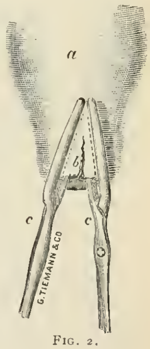

Fig. 2.

The advantages of these clamps are: (1) Rapidity of operation; (2) The prevention of the loss of blood; (3) Perfect and unfailing coaptation of cut surfaces; (4) Neater and smoother scar line; and (5) More rapid healing. Surgeons who have been accustomed to the old methods will readily appreciate the advantages of the instrument, while the novice will find in it a friend indeed.

I will say, however, some familiarity with the instrument, and a little practice, will be necessary in manipulating the clamps to the best advantage. The selection of a needle is of some importance; it should have a good curve and be of medium size. The Kelly needle serves a good purpose.

Sir George Critchett.—Sir George Anderson Critchett, the only British medical man to be honored with a title in the latest distribution of such distinctions, is reported to be, like the late Sir Morrell Mackenzie, a consistent patron and supporter of the drama. Mr. Sidney Carton, the well-known dramatist, is his brother, and Miss Compton, the actress, his sister-in-law. Sir George is one of the most distinguished ophthalmic surgeons in Great Britain, and has thoroughly earned the knighthood which has been bestowed upon him.

Tuberculosis	2[illegible]8	166
Typhoid fever	17	6
Cerebro-spinal meningitis	.	

Professor E. A. Schafer on the Structure of the Liver.—At a meeting of the Royal Society of Edinburgh, held on February 3, Professor Schafer of Edinburgh University read a paper on the "Existence Within the Liver-cells of Channels Which Can Be Directly Injected from the Bloodvessels." He drew attention to papers written by Professor Browicz giving the results of observations on the liver-cells, in which he concluded that in addition to the presence of intracellular-biliary excretory channels there were also special afferent nutritive channels in the liver-cells. Professor Schafer offered objective proof of this contention. He had found specimens in the Edinburgh University physiological laboratory of injected liver from the rabbit which clearly showed the intracellular nutritive canaliculi. On looking further into the matter he found specimens which had been left to the University by the late Professor Rutherford, some of which were apparently of this same rabbit's liver, while others purported to be from the liver of the cat. Some of these were labeled "Shows injection within liver-cell," and one of them bore the date 1886. Professor Schafer wrote to Professor E. W. W. Carlier of Birmingham, who at the date indicated was assistant to Professor Rutherford, to find out whether he could furnish any information with regard to the specimens. Professor Carlier wrote in reply that the specimens were injected by Simpson under his direction, and used for class purposes, and that he had first noted the canals and had shown them to Professor Rutherford, who, however, would not allow him to publish a note of them. Whatever might have been Professor Rutherford's reason in so acting, it was a matter for regret that the fact of the existence of intracellular canals in direct communication with bloodvessels should not have been made public. It was impossible to overlook the importance of the existence within the cells of any organ of vascular canals too narrow to admit blood corpuscles, but doubtless capable of conveying the fluid portion of the blood directly to the cell protoplasm.—*Scottish correspondent to Lancet.*

A Panacea Indeed.—The Surgeon-General's office is constantly in receipt of communications with regard to "sure cures" for disease, most of which are curiosities from both the medical and literary standpoints. One prescription recently sent in by a layman as a specific for dysentery contained opium in poisonous doses. The following letter, the chirography of which should be seen to be appreciated, is a fair type of a certain large class of communications:

"Sirgint of U S Army
Washington D C

Sir I seat myself to pen you a few lines to tell you that I have found the thing sought after this is to take Poison out of the Blood & still not impare what blood is left do do this with Purity & loose none this is the bigest invention in the world I can Cure all kind of diseases now if the government wants this kind of medacine they Can buy it & you know this is what they want yours truly

Prof J—— —— & —— Sts Omaha
write soon neb"

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended February 28, 1902:

SPECIFIC MEDICATION.*

BY ANDREW H. SMITH, M.D.,
NEW YORK.

IN a large proportion of cases calling for treatment the whole duty of the physician is comprised in efforts to alleviate symptoms, without any attempt to remove the underlying cause. This course is determined by one of three conditions. First, when we do not know the cause; second, when we know the cause and know it to be irremediable; third, when we know the cause to be transient and of such a nature that it may safely be left to itself.

In any one of these conditions our rôle consists simply in regulating the various functions of the body, so far as may be possible or necessary in order to maintain as nearly as practicable a physiological condition, and then to relieve pain or other distressing symptoms that may arise.

This has been termed treating the patient instead of the disease, and the observing of this distinction is sometimes claimed to indicate special sagacity in therapeutics. But there are morbid states, which evidently are but the working of a foreign agent which has obtained a lodgement in the body, which latter serves merely as the theatre of its operations. The activity of this agent then constitutes the disease, and the disease will continue so long as the morbific agent remains active. Such a disease we call specific, and the disease itself, as distinguished from the patient, calls for treatment.

The treatment in such a case necessarily implies the employment of some remedial agent that has the power of antagonizing the noxious principle at work in the organism. This antagonism may be chemical or vital, in its mode of action. More commonly it is the latter. The subtle relation that exists between the living cell and some forms of dead matter, though most real, defies all analysis, and our knowledge of it is, and probably always will remain, purely empirical. Why cocain should paralyze a sensory nerve, or strichnine should tetanize a muscular fiber, we do not know, and have no means of knowing. In like manner, we simply know the fact that the malarial organism cannot live in blood that contains an almost inappreciable quantity of one of the cinchona salts; but the reason for this we can scarcely conjecture. Other organisms do not show a like susceptibility to the drug in question, nor will this one as readily succumb to other drugs apparently more efficient as germicides. We can only assume that a a peculiar relation, that has a biological rather than a chemical basis, exists between the parasite and the remedy, and is along the line of the reaction between cell life and drug potency already referred to.

As yet, the list of diseases for which universally-accepted specifics exist is very limited, comprising certain infections and, perhaps, some other diseases not of parasitic origin.

It is to be observed that it is not claimed for a specific that its use shall be attended by success in every case. The most required is that in uncomplicated cases, and under proper conditions, a cure may be expected as a rule or, at least, that the disease may be held in check so long as the remedy is continued. Thus, it is rarely that syphilis can be so completely eradicated that the patient is secure against relapse if all treatment is definitively suspended. A pernicious chill may destroy life in spite of enormous doses of quinine. It is a common experience that the salicylates will not complete the cure of rheumatism after having controlled the early severe manifestations, and so on with regard to other specifics. And yet no one would venture to deny that in each of these diseases the remedy exerts a directly curative influence such as no other agent is capable of producing. What practitioner ever thinks of relying in the first instance upon any other than the generally recognized specific treatment in these affections, though we may be forced in the end to accept the aid of additional remedies.

But are we always to remain satisfied with the progress thus far made in the use of specifics? Is the lofty tone justified with which we are so often reminded that we possess no specific for this or that disease, and that the favorable results supposed to have been observed from the use of this or that treatment are illusory, or, at best, depend upon differences in the severity of the disease in different seasons and different localities? It would be well to remember that of the specifics upon which all rely with confidence one is scarcely a dozen years old as yet, and another came into use with the recollection of many who are still active practitioners of medicine. Is there any reason to assume that the list is to remain always as it is? May we not rather say, in general terms, that the prospect is favorable for an increase of the number of the remedies available for use as specifics, as the result of increased knowledge of the phenomena of cell life, on the one hand, and of the action of remedies on the other?

Thus far the field for specific treatment has been confined to diseases in which a foreign morbific element has been introduced into the system. An exception to this is myxœdema and its kindred diseases, the difficulty in this case being the absence of something furnished by the thryoid gland, and which is necessary to a proper action of the economy. The artificial supply of thyroid gland or its extract constitutes an efficient specific treatment for the disease and its congenors.

In regard to diseases having a parasitic origin, the problem is so to act upon the specific micro-organisms as to prevent a further production of toxin. Toxin already formed and absorbed into the blood is very speedily gotten rid of. This is shown by the prompt decline of temperature when a focus of infection is done away with. It is the continuous fresh supply of toxin that does the mischief.

Now, in the discussion of this problem we very often meet with the assumption that the remedy employed must be sufficiently powerful to destroy the pathogenic organism. But this is not necessary. What as would effect the destruction of the germ, but to inhibit its activity, and these are very different things. So different are they that Sternberg makes separate classes of those that prevent growth, which he calls antiseptics, and those that destroy the microorganism, which he calls germicides or disinfectants. Different strengths of solutions of the same agent may represent these two classes, and the strength of the latter class may require in some cases to exceed enormously that of the former. The mercuric chloride in a strength of 1 : 1,000,000 will prevent the development of anthrax spores, while destruction of these spores requires a strength of 1 : 1000.

---

*Read before the Association of the Greater City of New York, February 10, 1902. Previously read in part before the Practitioners' Society.

A further difference in favor of antisepsis within the body as distinguished from that observed in the laboratory, arises from the fact that blood-serum so long as it is circulating in the vessels of a living animal acts by virtue of its vital condition as an antagonist to bacterial growth. How powerful this antagonism may be we can only conjecture, as it ceases the moment the blood is withdrawn from the circulation. That it is considerable, however, is shown by the observation of Koch that bacterial filaments from a drop of blood in a case of anthrax soon perished in a 1 : 850 solution of carbolic acid, though if a similar drop of blood were placed in the nutrient broth and the same strength of carbolic acid were added the bacilli lived and grew therein.*

Another assumption which is exceedingly common is that for combatting germs within the body we must look to those agents that are relied upon for use as disinfectants outside the body, and it is claimed that safety in the use of these requires such a degree of attenuation as would make them inoperative. In this connection calculations are made as to the total weight of blood in the body and the ratio that any safe quantity of an antiseptic would bear to it.

But this reckoning involves two fallacies. In the first place, not one of the recognized specifics would be employed outside the body for its disinfectant properties, and in the second place quantities of the appropriate agent, amply sufficient for the purpose, are constantly being given as specifics with entire safety. It is to be remembered that attenuation of an antigermic solution is compensated for by longer exposure of the germ to its action, and that the conditions under which specific remedies are employed usually favor this prolonged exposure. As already said, the relation between the specific disease and the specific remedy is rather a vital than a chemical one, and is only remotely suggestive of open wound disinfection, which is almost necessarily chemical in its nature. These arguments are brought forward to show that the case for specific medication outside the few diseases for which it is universally admitted to be indicated is not so hopeless as it is commonly held to be. If dogmatic negation would yield to open-minded weighing of evidence, if hopeful leads would be carefully and persistently followed up, if the bacteriologist and the clinician would join hands in a quest for antagonists to disease, specific medication would perhaps add many new triumphs to match the wonderful achievements of pathology.

To illustrate my meaning, let me quote from a recent communication paraphrased in part from the article which it criticises.†

Speaking of pneumonia, the writer says: "This diversity in the death rate has given rise to false conclusions as to the result of various plans of treatment. Aside from such errors, conclusions equally false have been drawn from reasoning by analogy. In a recent authoritative publication it has been assumed that full doses of mercurials and other germicides may favorably influence the course of the attack by rendering the candidate an unfavorable culture medium for the pneumococcus."

Now this reasoning is not based on analogy. It is based on plainly stated facts, which the critic utterly ignores. Further on he says: "We only know four infectious diseases in which we are able to meet the causal infection. Malaria we can control by quinine alone, syphilis only by mercury and the iodides, rheumatic fever only by the salicylates or analogous substances, diphtheria only by its antitoxin. It would be a remarkable fact if croupous pneumonia—a disease due to a specific microorganism—should yield to a treatment by a number of different drugs selected to meet the cause." . . . "Nor does it seem desirable to repeat the futile experiments already made in regard to pulmonary tuberculosis, scarlet fever, and other acute infections."

Why our critic should insist that there cannot be more than one specific for each disease it is difficult to see. And it is conspicuously untrue in the case of malarial fever, which may be successfully treated with arsenic, iodism, carbolic acid, ammonium picrate, and perhaps some other remedies. However the fact may be, to say that there is no specific for pneumonia, because so many different agents will inhibit the germ upon which it depends, is to argue that a thing cannot be done because there are so many ways of doing it. Our critic continues: "The effect of indifferent antiseptics and germicides upon parasitic microorganisms must bear a definite relation to the mass of the blood in which they are diluted, which may be roughly estimated at twelve to fourteen pints in the adult." But what definite relation does half a drachm of quinine, or of potassium iodide, or two or three drachms of a salicylate, or a dose of antitoxin bear to twelve or fourteen pints of blood? Who asks such a question in the presence of a case of malarial fever, of syphilis, of acute rheumatism, or of diphtheria? If the use of these specifics had had to wait until a definite relation between their dosage and the total quantity of the blood had been established, how much should we have profited by them up to the present time?

Our critic proceeds with quotations to fortify his paralyzing arguments:

"In the long run the expectant method of treatment, which interferes only as occasion requires, is followed by a far lower mortality than misplaced attempts to jugulate the disease." "Pneumonia is a self-limited disease, which can neither be aborted nor cut short by any known means at our command." "There is no specific treatment for pneumonia. The young practitioner may bear in mind that patients are more often damaged than helped by the promiscuous drugging which is still only too prevalent." "The less the physician interferes with the normal course of pneumonia, the greater the probability of a favorable termination."

Our critic omits all mention of the numerous reports of cases treated with sodium salicylate, to which reference will be made hereafter, although many of them were discussed in the article to which he alludes.

He also ignores the fact, plainly stated in the same article, that the treatment in question substitutes lysis for crisis as the habitual mode of defervescence, the lysis, when the treatment is begun early, occurring in advance of the usual time of crisis.

Such testimony cannot be dismissed with a wave of the hand by however august an authority. Nevertheless pronouncements of this kind are certainly not in the line of progress, and I am glad to note the following reluctant concession: "Notwithstanding these ob-

†New York *Medical Journal*, November 2, 1901.

jections, it must be conceded that thoughtful researches in the direction of specifics are justifiable."

How "justifiable" on purely theoretical grounds, not only in regard to pneumonia, but also in regard to other specific diseases depending upon a microorganism, we have already considered briefly. But it will be interesting to examine, in a very few words, the special *a priori* reasons for regarding pneumonia as a promising field for specific treatment, and how far they accord with the pessimistic attitude which these writers assume.

In this disease we start with a microorganism less hardy than any other we are acquainted with. Indeed, its resistance is so feeble that it is with great difficulty that it can be cultivated in the laboratory. It should, therefore, be peculiarly susceptible to antimicrobic influences. Next, the exudate which supplies the medium in which it grows is separated directly from the blood, and must contain its full proportion of any substance in solution in the blood. Third, the lung transmits, through its lesser circulation, all the blood that passes through the vastly greater systemic circulation, thus bringing a concentrated influence to bear upon the microorganism in the pulmonary alveolus, as compared with the influence exerted in any other portion of the body.

Thus, we have conditions very favorable for acting directly upon the germ, so that, theoretically, the aspect of the case is encouraging. And from the clinical side, accumulating experience, as already stated, seems, in a considerable measure, to support the theoretical deductions.

Quite a number of drugs appear to act more or less specifically in pneumonia, but the one which seems to have accomplished the most thus far is the salicylate of sodium.

So far as I know, the first to report upon this as a remedy in pneumonia was Liegel in 1898. He treated seventy-two cases occurring in miners, many of the cases being very severe and in very unfavorable conditions. There was not a single death, while under the symptomatic treatment alone the mortality had been very great. Ferguson treated 106 cases with six deaths, Sebring collected 125 cases with two deaths. Smaller groups of cases equally favorable to the treatment have been reported by numerous observers.

Now, when we consider that the usual mortality from pneumonia is from 15 per cent. in private practice to 25 to 30 per cent. in hospitals, it is begging the question to say that because in these series so many recovered, therefore the type of the disease in all must have been very mild, or that the diagnosis in the great bulk of them was faulty.

As to mildness of the disease, Sebring says:* "It is not apropos to say that these results came from the nature of the cases, or the mildness of a benign epidemic, for it was not so. The cases were almost without exception severe ones, and some of them extremely desperate. In the same localities, with the same surroundings, and with the regular forms of treatment, my medical brethren had many deaths. I had seen before and have seen since a fair amount of pneumonia, and that series of cases was of more than average severity. More than twenty-five of these cases were in patients over sixty-five years of age. Four of them were over eighty, and one was a man of eighty-four years of age and an habitual drunkard."

So much for the sodium salicylate. The carbonate of creosote, also, is received with a good deal of favor as controlling the action of the pneumococcus, and I have found it nearly as efficient as the salicylate of sodium.

It can be given in quantities of two or three drachms or more a day without the slightest inconvenience, and continued until all disposition to rise of temperature has passed. It will usually bring about a lysis commencing twenty-four hours after the administration is begun. It is not disturbing to the stomach, and is to be preferred when that organ seems inclined to be irritable.

I should select it also in cases of considerable depression, when the sweating caused by the salicylate would be objectionable.

Going back as far as November, 1899, in an article on pneumonia in the *Medical News*, after citing a number of writers and my own experience, I recommended that family physicians keep their families supplied with carbonate of creosote or with a salicylate, preferably the former, so that, in case of indications of pneumonia, such as a chill with pain in the chest, the drug may be begun at once, and possibly the development of an attack prevented.

At the Presbyterian Hospital in this city, there have been, at the time of writing, thirty-one cases of croupous pneumonia treated since December 15, a period of forty-seven days. Of these, twenty recovered and eleven died. Of the latter, five were moribund on admission, one had carcinoma of the liver, one had chronic bronchitis and emphysema, one had stricture (malignant) of the œsophagus, and one died of endocarditis. There were, thus, only two cases in which any expectation of recovery was possible when they entered the hospital.

Of the thirty-one cases, twenty-eight were treated with carbonate of creosote, ten grains being given every two hours. Three received none of the medicine; of these two recovered, and one died three hours after admission.

Of those treated with the carbonate of creosote, eighteen recovered. In thirteen of these the defervescence was by lysis; in five by crisis. This proportion contrasts strongly with the usual termination of the fever, which is, as stated by Osler in his definition of pneumonia, "abruptly by crisis."

In this series we have twenty cases, excluding those already moribund and those complicated with conditions necessarily fatal in the presence of any severe acute disease. Of those twenty cases, two were fatal, a mortality of 10 per cent., chargeable to pneumonia. As to the severity of those cases recovering, one had a temperature of 106.2, one of 106, two of 105.6, three of 105.4, two of 105.2, and one of 105, thus ten of the eighteen ranging between 105 and 106.2 The average time between the invasion of the disease and the beginning of the treatment was three and one-eighth days for those who recovered and four and one-sixth days for those who died.

In March last a paper was published in the MEDICAL RECORD entitled, "Creosote in Pneumonia: A Résumé," by I. L. Van Zandt of Fort Worth, Texas, from which I quote some of his own experiences and some of his citations from European observers: .

"In June, 1898, I read a paper on this subject before the North Texas Medical Association. This was received by some with incredulity, they citing the fact that 'all authorities' (whatever that may mean) said that pneumonia was a self-limited disease, and must run its course. Others were willing to make a trial on my report, reinforced by that of several gentlemen present, who had adopted the treatment at my suggestion.

"Quite a number of those present and others who read the published paper, have reported satisfactory results.

"During all this time I have had cases in which the fever was gone in from twenty-four to forty-eight hours, and I am now somewhat disappointed if my patient is not ready for dismissal by the third or fourth day. In cases which persist longer there is generally an amelioration of symptoms, and the coming of an appetite, to which I was formerly a stranger in pneumonic cases. There is generally a gradual decline in the fever, with only slight moisture of the skin, a critical sweat being rare.

---

*MEDICAL RECORD, April 22, 1899.

"Another thing I, as well as others, have found, is that if the medicine is discontinued as soon as the fever has ceased, there will likely be a recurrence of all the symptoms. Hence I continue the medicine at longer intervals for two or three days after subsidence of the fever.

"At the Pediatric Congress held in Marseilles in 1898, Dr. Cassoute, physician-in-chief to the Marseilles hospitals, gave a brief preliminary notice of his new method for the treatment of pulmonary affections. The method consists in the continuous administration of fairly large doses of creosote carbonate. In most cases a typical fall of temperature occurred during the first twenty-four hours of treatment, and if the creosote carbonate were continued for a sufficiently long period of time, the apyrexia will be a permanent one. The temperature curve rose again, however, when the drug was discontinued, before the auscultatory signs had disappeared. Relapses and sequelæ, so frequently seen under other methods, were entirely absent.

"Dr. Charles F. Stokes, United States Navy, in the *Brooklyn Medical Journal*, August, 1900, says: 'I have employed it in several cases with excellent results. Early treatment offers most satisfactory results.'

"Dr. J. W. Frieser of Vienna, in the *Aerztliche Central-Zeitung*, says: 'The treatment of acute inflammatory affections of the respiratory passages with the drug has yielded entirely satisfactory and even brilliant results in my hands. Both clinician and practical physician are fully aware that we formerly possessed no remedy that was even half way satisfactory in its action upon pneumonic disease process. Our entire therapeutic armamentarium was symptomatic and expectant in its nature. But it is an unmistakable advance if experience teaches us the employment of a remedy which has an influence on the disease process itself, and possibly upon the specific organisms that cause it. The favorable effects of creosote carbonate upon the various forms of pneumonia have been noticed by others as well as by me, and they are undoubtedly due to antiseptic and antibacterial action of creosote, which, in the form of the carbonate, can be introduced into the body in sufficient quantity and in innocuous shape. Besides this, it has a favorable influence on the heart and the patient's general condition, it causes, as I have often noticed, a rapid fall of temperature and retrogression of the local symptoms. The gastro-intestinal canal is in no way injured by its use. In some cases the inflammatory processes in the lungs get well with such extreme rapidity that the method might be called an abortive treatment. The temperature rapidly sank to normal, the general condition noticeably improved, the tongue cleaned and became moist, and the appetite returned.'

"Dr. Wilhelm Meitner, in the *Medicinisch-chirurgisches Centralblatt*, June 22, 1900, says: 'The most important effect of the creosote treatment is the surprising fall of temperature a few hours after its administration is begun; it becomes normal in two days or sooner. With this the general condition improves, the pulse becomes better, the breathing quieter, the cough is lessened, thirst ceases, and the dryness of the mouth and lips disappears.'

"Dr. M. Eberson, in the *Aerztliche Central-Zeitung*, July 7, 1900, says: 'Two things may therefore be claimed for the creosote treatment. In the first place, it cuts short the disease in a most remarkable manner. In the next and more important it causes complete resolution of the disease focus, so that the sequelæ, more especially after catarrhal pneumonia, will not be so important in the future as they have been regarded in the past. Nor does it seem to me to be unimportant, considering the bacillary origin of pneumonia, that the sputum and excreta are voided disinfected, so that the contagiousness is reduced to a minimum. It is incontestable that the creosote treatment of pneumonia is a very important advance in practical medicine.'

"Now, with this array of testimony reinforcing my own observations for the last seven years, I trust that the members of this association will not consider me oversanguine when I express the opinion that the use of creosote or carbonate of creosote in the treatment of acute pulmonary inflammations is one of the greatest life-saving discoveries of the century just ended."

Among many other commendatory notices of this drug for use in pneumonia is one by Professor Leonard Weber in the MEDICAL RECORD of November 2, 1901. Within a short time he had treated nine cases with it, with one death.

Since the above was written, Professor W. H. Thomson has published in the MEDICAL RECORD of February 1 the details of eighteen cases treated with creosote carbonate, with one death. He notes what I have remarked above, that the defervescence in these cases, as in the use of sodium salicylate, is much more frequently by lysis than by crisis, the proportion in his series being as twelve to five.

Among the diseases for which it would be most desirable to possess a specific is influenza. Not only is the disease in itself dangerous to life, but, with the single exception of tuberculosis, it probably entails more invalidism than any other with which the community is afflicted. It affects a vast number of persons, and a large proportion of these do not fully recover their health until months or years have passed. How constantly do we hear the complaint, "I have not been well since I had the grippe."

This persistent derangement of health is very suggestive of continued infection with the specific organism, much as is the case in chronic malaria, though it is doubtful if the germ could be demonstrated in the tissues after it has disappeared from the mucous surfaces.

In the treatment of influenza, the relief that is obtained at first from the coal-tar preparations is not continued during the later stages, and we are left to do the best we can with general hygienic measures, tonics, etc. And yet something might be found, perhaps in the most unexpected quarter, which would search out and remove the morbific element in the case. The condition being a somewhat chronic one, the treatment might require to be protracted, but if the almost interminable sequelæ so often observed could be overcome as the result, it would be of inestimable value.

Dr. S. Henry Dessau of this city, as also Dr. Arthur Wigglesworth of Liverpool, seem to have made no small progress toward realizing this desideratum. The former published a paper in the MEDICAL RECORD of September 12, 1896, and another in *The Therapeutic Monthly* in May, 1901, in which he gave the strongest evidence of the great value of large doses of carbolic acid in the treatment of influenza. The latter, in the *Lancet* of April 3, 1899, recommends it with equal emphasis. Both insist upon the safety of the drug even in very large doses.

Another disease which offers a tempting opportunity for specific treatment is scarlet fever. We have had within the last four or five years two or three communications in the *London Lancet* from Dr. Arthur Wigglesworth, the writer already mentioned, in which he has described, in this disease, also, very remarkable results from exhibiting large doses of carbolic acid. The treatment amounts to making this dread disease one of extremely slight mortality, while it prevents in great degree its spread by infection.

He presses the remedy designedly to the point of causing carboluria, and maintains this condition until the fever has fully abated. So far from this proving injurious to the kidneys, he has had only three cases of renal implication in all his experience, and his cases, in other respects, have been exceedingly mild. Moreover, the infection communicated by these carbolized patients is extraordinarily light, but yet sufficient to confer permanent immunity, and he urges that it is better to let children take the disease in this modified form, rather than to leave them to the chance of contracting it later in its normal virulence. When this is refused, however, light carbolization of those exposed gives immunity for the time being.

He has followed this plan for twenty years almost without a failure, in a practice in which he has attended over 3,000 births, and he informs me, in a private communication, that he has never had a single mishap from the carbolic acid. That this practice has not been followed up by other practitioners, is another illustration of the indifference or timidity of the profession, perhaps from discouraging teaching by admitted authorities.

In support of the innocuousness of pure carbolic acid, I have several observations of my own, made four years ago. Dr. Wigglesworth gave to children from one to six grains, according to age, every two hours, freely diluted with water. I gave to adults rapidly increasing doses until the largest amount in twenty-four hours was respectively 154 grains in one case, 112 in one, 108 in one, 72 in one, 60 in six, and 57 in one, while five cases received from 4½ to 40 grains. Not one of these showed any ill effects. Two who had albuminuria previously were not made worse. One with general sepsis died on the eighth day after the administration of the acid was begun. I was encouraged to persevere in this instance by the ultimate rescue of a patient with malignant pustule, reported in the *Lancet* just at that time, in which much larger doses had been given than any I had ventured upon.

It will be remembered that Declat gave very large doses hypodermatically in the treatment of intermittent fever, and that he insisted, as the result of a large experience, that with a pure acid no danger whatever was incurred.

The discoloration of the urine was formerly considered to be due to disintegration of red corpuscles and to require an immediate suspension of the drug. It is now known that this is not the case, and that the remedy can be pushed far beyond this point with safety. This is also true of creosote, and it seems quite possible that the usefulness of these two agents as internal antiseptics, or, if you please, as specifics, may be greatly enlarged by the recognition of this fact.

The damage inflicted by the gonococcus when it has penetrated into the deeper structures of the body calls earnestly for a treatment that shall do more than to leave the infection to itself, while wrestling with a so-called inflammation. We are told that a solution of mercuric chloride, 1 to 20,000, applied for a few minutes, at intervals during the day, is an effective strength for irrigation in the acute stage of "urethretis." This being true, might not a perpetual irrigation through the medium of the blood be effective, after the coccus has worked its way into the deeper tissues, and this without employing an unsafe quantity of the drug? Before the days of antitoxin, our distinguished colleague, Dr. Jacobi, advocated a treatment for diphtheria with this agent, administered by the stomach, in the belief that it would search out and inhibit the bacillus, and he was able to adduce clinical facts in support of his view. Would it not be well carefully and patiently to test such a method, in pelvic or articular gonocosis, employing this or some other alterative drug?

More and more we are losing faith in the chemical theory of gout and rheumatism and incline to the belief that these allied diseases are produced by some infective principle. In the case of rheumatism this belief derives strong confirmation from the therapeutic side. Only less confirmation is afforded by the effect of colchicum in gout. In neither of these diseases has a specific organism been demonstrated. But this may be due to the lack of a suitable culture medium to represent the special tissues in which the poison in either case develops its activity. As the pneumococcus will not thrive in the secretion of a mucous membrane, but will thrive in that of pavement epithelium, so there may be a microorganism that finds its proper habitat in the synovial tissues about the joints, but will not grow in any of the media now in use in the laboratory.

This reasoning applies with equal force to other infectious diseases for which a germ has not yet been found. Indeed, there is a growing tendency to refer all this class of diseases to microbic origin. A further development of the magnifying power of the microscope may have to precede the solution of this problem, just as the bringing out of the one-twelfth immersion lens was a necessary preliminary to our present bacteriology.

But in the meantime a survey of the field seems to suggest that all the known pathogenic bacteria should be studied, not so much to learn how to grow them as to learn how to inhibit their growth. And in the quest for inhibiting agents each germ might be interrogated with a list of articles, perhaps not thought of now as germicides, since no one can tell what unexpected results might not be attained by purely empirical methods.

While the bacteriologist is at work in his laboratory, the clinician, on his side, has a field for action. Carefully-conducted experiments will show that the present dosage of remedies may be safely exceeded in some cases, or that objectionable effects may be avoided by combinations of remedies which yet will leave the specific action intact.

The entire range of infectious diseases, as well as those of which myxœdema is the type, invites us to this kind of investigation; and to urge its importance and stimulate hopefulness as to an ultimate substantial degree of success is the object of this paper.

Automobile Speed Bill.—The Cocks Automobile Speed bill finally passed the Senate on March 6. Originally the offence of driving an automobile faster than eight miles an hour within city and village limits and fifteen miles an hour without was punishable as a misdemeanor by a fine of $50 and imprisonment for six months. The bill as just passed provides that anyone who operates an automobile faster than eight miles an hour within a city or village where local ordinances do not otherwise provide, and faster than twenty miles an hour outside of city or village limits, or faster than four miles an hour on any bridge, is guilty of a misdemeanor and shall be fined for the first offence not exceeding $50 and for the second offence not exceeding $50, or by imprisonment for a term of six months, or both.

MELANCHOLIA SIMPLEX AND MELANCHOLIA TRANSITORIA SIMPLEX.*

By RALPH LYMAN PARSONS, M.D.
NEW YORK.

Of all abnormal mental conditions, states of depression are undoubtedly the most frequent. In fact, not only is mental depression at some time a prominent symptom in almost all cases of mental alienation, but many persons suffer from such depression for longer or shorter periods of time, and in various degrees, who are never suspected of being insane, nor even of being especially depressed in mind. The greater number of these speedily recover. Indeed, the majority of mankind are so constituted that they are not likely to become insane under any mental strain however great, nor under the most serious disabilities, short of organic disease of the brain itself.

In some of these cases, however, although typical insane delusions are never manifested, the mental depression does so dominate the mental faculties as to constitute the disease commonly known as simple melancholia, or melancholia without delusion. And this type of mental disease is of special importance for the reason that with prompt and judicious care and treatment the ratio of recoveries is greater than in any other, that the sufferings are more intense, and that suicidal impulses, or at least mental suggestions of suicide, are present in almost every case.

Of forty-four consecutive cases of simple melancholia admitted to a single hospital for the insane, no less than twelve had already attempted suicide; six, certainly, and probably two or three of the others, did commit suicide after their discharge as recovered, or as improved, during subsequent attacks or exacerbations, eighteen had fully recovered at the date of their discharge, twenty had greatly improved, and of these last the greater part made a complete recovery after their discharge. Under favorable circumstances and with early and judicious care and treatment, as great a ratio as 90 per cent. of simple melancholia, or even more, may be expected to recover.

That the sufferings of this class of patients should be more intense, and that the disposition to commit suicide should be greater than in most other forms of mental alienation, may be explained, in part, by the fact that the brain deterioration is less, and so that there is greater capacity for a full realization of their sufferings, and it should not be forgotten that the physical distress experienced by these patients, while overshadowed by, is hardly less than the mental. The normal sense of well-being is lost, the whole nervous system is in pain; the vital functions are disturbed and impeded; the whole body is sick. Even in cases of agitated melancholia there can be little doubt that the intensity of the suffering is less than in cases of simple melancholia. In the former the expression has become more or less automatic, and the consciousness of self has become more or less blunted by the exhaustion of the nerve centers. Patients who have recovered from melancholia with stupor, and who had manifested an expression of overwhelming misery, sometimes speak with the greatest equanimity of the condition from which they have recovered, showing, at least, that their sufferings did not make a lasting impression.

Now it will not be claimed that every person who becomes greatly depressed in mind has lost the use of his reason. Some even conceal their mental suffering from their nearest friends. Their nervous system is so strongly constituted that they successfully resist the action of depressing influences which would overwhelm those more feebly constituted. After a short struggle against adverse influences and feelings they recover from their depression and find themselves possibly stronger than ever as a result of the successful contest.

Nor is it true that all persons who commit or attempt to commit suicide are insane. The fact that the instinct of self-preservation is the strongest of all our instincts has led many to think that all suicides are insane. But this is not the case. It is not even probable that the majority of those who commit suicide are insane. With some the instinct of self-preservation has been overcome by a course of dissipation and wrong living. Some are influenced by example. Epidemics of suicide in communities and in armies have arisen chiefly from this cause. Some deliberately and philosophically, as they think, have adopted the doctrine that suicide is a legitimate and rational resort whenever the ills of life press too heavily. Others have never learned to control their emotions, and so are liable to commit a foolish and desperate act on the impulse of the moment. Some commit suicide through cowardice, or through simple lack of fortitude to endure an impending evil. In some cases the suicidal act is committed with revenge as the chief impelling motive. This is probably true of many cases of child suicide. A child has suffered some real or fancied injury from a parent, for instance, pictures to itself the agonizing grief the parent will feel on learning of its death, and commits suicide for the purpose of causing such grief. Suicides are sometimes deliberately committed for the benefit of others, as to save life, or as when a person secures an insurance on his life and then commits suicide for the benefit of another.

But, after all these and similar cases are eliminated, there undoubtedly remain a large number of suicides who are either in the early stage of simple melancholia, or who may be considered as in a state of transitory melancholia. In order to facilitate the early recognition of these cases of simple melancholia, it might be of advantage if the term melancholia transitoria simplex were added to the nomenclature of insanity, as the designation would naturally call attention to the fact.

These attacks of transitory melancholia, which are for the most part unrecognized, or at least, unrecorded, unless they culminate in a suicidal or homicidal act, are liable to occur in persons who have suffered a sudden and severe shock, as from loss of property or friends, from disappointment of the affections, from domestic infelicities, from great and prolonged anxiety, from physical and mental exhaustion, or from similar causes.

Considerations such as these should serve in some degree, at least, to bring about the early care and treatment that are so important in these cases. Intimate friends, it is true, may be the last to recognize the gravity of the situation; but the skilful medical adviser may discern the impending danger, and so bring the matter to their attention.

It may be objected that no such type as melancholia transitoria has ever been differentiated, that melancholia is chronic in its nature, that what appear to be sudden accessions of the disease are only manifestations of a condition that has already existed in a latent state for a considerable period of time. While these objections may be well founded in most cases that come under our notice, there are undoubted cases of extreme mental depression, with strong suicidal impulses, which are sudden in their onset, and which prove to be of limited duration. They are simply unnoticed, forgotten, and unrecorded, on account of their limited duration. A considerable number of cases have come under my own observation, in which an attack of simple melancholia was almost instantaneous in its accession. In like manner, sudden recoveries have been observed after the melancholia had existed for longer or shorter periods of time, even for several years. Such sudden attacks and sudden recoveries, if separated by only a short period of time, constitute the cases to which attention is here directed as of great importance in regard to recognition and management, and as proper to be included with simple melancholia, and classified as melancholia transitoria simplex.

---

* Read before the New York County Medical Society, February 24, 1902.

It is well to note, in this connection, that many cases of simple melancholia cannot be considered as insane, in a strictly legal sense, while they do need the strictest medical care, supervision, and control; that is, they are able to make a rational and equitable will, or to manage business affairs intelligently, whenever they can be brought to give their attention to such matters at all; while, at the same time, they would fail to take proper care of their own persons, or may need to be restrained from doing themselves an injury. And so, these two questions, the medical and the medico-legal, require a separate consideration in each individual case.

But in saying that many cases of simple melancholia are quite competent to transact ordinary business with a good degree of judgment, and to converse on the topics of the day with intelligence, it is not to be implied that the reasoning power and the will are not involved in the breakdown. On the contrary, all the mental faculties are involved. While, on the one hand, there is no such condition as total insanity, on the other there is no case of insanity that does not involve all the mental faculties to a greater or less degree.

Nothing has been said thus far of the differential diagnosis between simple melancholia and other forms of melancholia. It has already been suggested that many cases which are usually considered and treated as simply laboring under a slight and temporary mental depression, ought really to be considered and treated as being in a state of melancholia. In these cases the diagnosis, which may be involved in no little difficulty, will often be a matter of judgment in which expert diagnosticians would disagree; for it should be remembered that there is no exact line of demarcation, no unmistakable symptom, on which such diagnosis can be founded. But the following considerations will be of value as aids in distinguishing ordinary mental depression from simple melancholia, as that, in the former case the depression is not extreme; that it does not dominate the reason, the will, nor the actions; and that it holds a natural and usual relation to an existing cause. In melancholia the depression is extreme, and is disproportionate to any existing cause.

Since the distinction between simple melancholia and delusional melancholia depends upon the existence of delusions in the latter case, and since certain kinds of delusions are of no weight whatever in determining the existence of insanity, while others are of great weight, or may even be pathognomonic, it becomes of importance to define, as clearly as possible, the characteristics of these different sorts of delusions.

Delusions are simply false or erroneous beliefs. For study and comparison, they may be conveniently classed in three categories: (1) Those which are not evidences of mental unsoundness at all; (2) Those which are pathognomonic of the existence of insanity, and (3) Those which may or may not be evidences of insanity. To the first class belong those false beliefs which are adopted on the testimony or teaching of others; such as are founded on a faulty observation of actual conditions, occurrences, or events; and such as are the simple outcome of ignorance, and which may be corrected by a more extended knowledge. And so, erroneous beliefs in regard to doctrines in religion or politics, or in regard to history or natural science, are not, in themselves, evidences of insanity. All men, however intelligent, may entertain and do entertain such erroneous beliefs.

It may be stated in a general way that erroneous beliefs which are entertained on account of the teaching, authority, testimony, or in accordance with the beliefs of others, and beliefs in matters which are not susceptible of scientific demonstration, cannot safely be considered as evidences of insanity.

To the second class belong those false beliefs which originate in the subject, which for the most part concern the subject, which are held by the subject alone, which to men of ordinary intelligence are evidently false, and which the subject cannot correct by investigations and reasonings of his own, nor by the advice, the assurances, and reasonings of others, as, for instances, the delusion that the throat is so contracted as to prevent the passage of food or drink, or that the brain has quite wasted away, in the case of melancholics. Delusions such as these may be considered as pathognomonic of the existence of insanity.

The third class of false beliefs, in melancholics, spring from and have their foundation in the depressed state of the feelings, and are, to some extent at least, adopted as an explanation of the mental and physical depression from which they suffer. These beliefs, such as that the subject will be an inmate of the poorhouse, that he is an intolerable burden to his friends, that he is causing disaster to their reputation or business, that the future is hopeless, or that he has committed the unpardonable sin, are not pathognomonic of any type of insanity. Indeed, they may be, and are, held by persons who cannot be considered as insane. They may be so deeply seated, so dominant, so utterly without reason, and so at variance with the habitual way of thinking of the subject, that they should be classed as typically insane delusions, or they may be so trivial and changeable in character as to justify classing them with ordinary false beliefs.

It should not be forgotten that as there is no fixed line of demarcation between normal mental depression and simple melancholia, nor between simple melancholia and delusional melancholia, so also there is no exact point of distinction between the different grades of delusions. Hence, in this regard, borderline cases frequently arise about the nature of which skilled experts honestly differ.

The average duration of attacks of simple melancholia is probably longer than is usually supposed, for while many recover in a few weeks, or even days, and while the majority of cases may be expected to recover in from six to twelve months, in other cases the melancholia may continue for three, five, or even ten years before recovery takes place.

It being the especial object of this paper to call attention to states of mental depression with reference to their frequency, early diagnosis and curability; to the great danger of suicidal attempts, not only during the height of the disease, but also before the seriousness of the patient's condition is usually recognized, and also before convalescence has been fully established; to the fact that melancholia simplex is sometimes sudden in accession and brief in duration, without doubt including many cases of suicide which have not been recognized as insane; and to suggest the adoption of the term melancholia transitory complex as a means of especially directing attention to this class of cases—a few suggestions only will be made in regard to management and treatment.

The medical adviser who finds his patient in a state of decided mental depression should make an early and exhaustive study of his condition and of the circumstances in which he is situated, in order that there may be no delay in adopting such methods of management and treatment as may be required. The preliminary safeguards, management, and treatment must usually be conducted at the home of the patient, whether the attack be gradual or sudden in its onset. In the former case there may be difficulty in the diagnosis, and the latter may be one of transitory melancholia from which a speedy recovery may be expected. But while an unnecessary or premature removal from home should be avoided, such removal will usually be found advisable, for the reason that home influences and associations have an intimate relation to the causes of the depression, that the relations of the patient to the other members of the family have become changed and restricted, or that the relatives, by the very reason of their relationship, are least of all fitted to continue in intimate association with the patient. They may be too sympathetic or too weak to exert a favorable influence, or they may be too intolerant of conduct which they think the patient might avoid, if he would. And then it must be taken into consideration that, wherever hereditary influences exist, others of the family may suffer from the hereditary taint, and so be themselves injured by too close association with, or by undertaking the management and care of their relatives.

Whether, in case it is found advisable to remove a patient from his home, the choice of a domicile should be a public hospital, a private hospital of large capacity, a private hospital with accommodation for a small number of patients, or private care as a single patient, will, for the most part, depend upon the pecuniary resources of the patient; but there are important considerations in favor of treatment in a well-equipped hospital, with its trained service and with competent physicians in constant attendance.

During the early stages of the disease, what is known as the rest cure, thoroughly practised as taught by Dr. S. Weir Mitchell, is often of great service; but this mode of treatment should not be too much prolonged, lest the monotony and the limited associations give rise to delusional ideas or to still greater depression, as sometimes happens.

Later on, or when the rest cure is not indicated, the time should be as fully occupied as possible; at first in a passive way, with things that can be done to or for the patient, afterwards by things which can be done in association with others, or entirely by themselves. Those occupations are most beneficial which have the accomplishment of a definite object in view, useful occupations being most beneficial of all, when the condition of the patient and his previous habits permit. As an open-air life is in itself beneficial, occupations in the open air are especially advantageous. Relaxations and amusements have their important uses, and should be judiciously prescribed.

After an attack of melancholia has become established, traveling is rarely advisable. The opportunity for such rest and treatment as may be required would be lost, while a suitable hospital might not be at hand in case of an exacerbation of the symptoms. Traveling, to be of service, should be undertaken under suitable attendance and with proper medical supervision, if possible, either before the mental depression has become a state of melancholia, or after the condition of the patient has so improved that convalescence has already fairly commenced.

But whether the patient be treated at home or at a special hospital, the prevention of suicide demands immediate and careful attention, and it is not to be inferred that because melancholic patients are quiet and may make no mention of wishing for death there is no danger of suicidal attempts. On the contrary, those who openly threaten to destroy themselves seldom make a determined attempt. Still those who do threaten to injure themselves may make the attempt under a sudden impulse, or when suitable means may be unexpectedly offered. A favorable opportunity is a strong incentive to the suicidal act, and especially when the patient is left alone even for a limited period of time. The melancholic patient may cunningly seek the opportunity of sending his nurse or attendant away on some plausible pretext, and then embrace the opportunity thus offered. The presence of other insane patients, even, may be an efficient preventive. Hence, melancholic patients should be under efficient supervision at all times, at least until it has been established that suicide is not likely to be attempted. Suggestive means for a suicidal attempt should, so far as possible, be removed.

It should be remembered that the suicidal impulse is usually much stronger at certain times than it is at others, as, during the early morning hours, especially after what may seem to have been a more than usually refreshing sleep; on retiring at night, during the catamenial nisus, in women, and in certain sorts of weather. In this last regard it has been observed that dull or even inclement weather is more in consonance with the feelings of melancholic patients than weather which is exceptionally fine. In like manner, it has been observed that while music of a jolly or lively character has had a tendency to deepen the depression in melancholics, music of a more quiet order, but still in the major key, has had a favorable influence.

The methods to which melancholics resort for self-destruction are varied and numerous, viz., by suspension, by submersion, by swallowing poison, broken glass, or other injurious substances; by precipitation from heights; by means of cutting instruments, by suffocation, and in many other ways. A strip of cloth attached to a nail in a wall or to the bedstead, or a basin of water may suffice for a suicidal attempt. Any and all such means should, as far as possible, be foreseen and removed, and especially those to which the patient has already shown a disposition to resort. And yet, strict supervision by and companionship with others is the only efficient safeguard.

As a preliminary to medicinal treatment, a thorough physical examination should be made, lest some obscure ailment be overlooked, and in order that all obstructions to the general health may be removed as soon as possible by appropriate treatment. Even if no organic disease should be discovered, it will usually be found that the digestion is impaired, that the bowels are sluggish, that some degree of autoinfection exists, and that the general innervation is defective. A mere mention of these points is sufficient to indicate the nature of the remedies required.

Assuming that the digestive organs are in a healthy condition, these patients require to be well fed. Feeding to repletion, even, may be of the greatest service, at least until the normal weight has been attained. In order that no mistake be made, the weight of the patient should be taken at frequent intervals.

All the means at our disposal should be used to secure prolonged and refreshing sleep, and without the use of drugs, if possible; such as an open-air life, baths, massage, properly ventilated sleeping rooms, a light meal on retiring at night, and again in the early morning, or in the middle of the night, if the patient becomes wakeful and restless. The patient should take a recumbent posture, at a suitable hour, whether feeling sleepy or not, and should remain in bed during the usual hours of normal sleep. An hour or two of sleep or of recumbency, during the day, will promote rather than hinder sleep on the succeeding night. The theory that persons who suffer from insomnia may as well sit up, walk about, or read, if they do not feel like sleeping, is usually a mistake in practice. The habit of sleep is best secured by sleeping; and for this a suitable posture and surroundings are important aids. If the use of hypnotic drugs should sometimes be found advisable, frequent changes of the particular drug or combination of drugs used should be made, lest a drug habit should be established, or their influence become impaired or lost.

Especial regard should be had to the moral treatment. In many, if not in most cases, this is even of more importance than the purely medicinal treatment. The patient should at all times have a suitable companion, an important part of whose duty it should be to engage the patient's attention with objectivities. If possible, he should be actively employed; and, it may be repeated, that of all employments those which accomplish some useful object are the best. The general tone of the patient's associations and surroundings should be encouraging and elevating in character, but not too much above the plane of the patient's own feelings. While the associates should be cheerful in manner and conversation, they should not indulge in hilarity.

With all this, the attending physician should have and should appear to have a lively and hopeful interest in the welfare of his patient. His expressions of hopefulness, his cheerful demeanor, assurances of ultimate recovery, his insistance that physical disease, a state of nerve exhaustion, is at the foundation of his patient's malady, from which in due time a full recovery may be hopefully expected, is of the utmost importance. The moral influence of the physician, added to that of those persons who are more constantly associated with the patient, will oftentimes prove as beneficial as any and all other means employed.

The Poisonous Properties of Mountain Laurel.—H. H. Rusby reports a case of the poisoning of twenty-seven sheep, in which only the leaves of mountain laurel could have been the agent. The symptoms observed in the animals indicate that the poison is a stupefying narcotic and a depressor of the motor system, the centers chiefly being affected and the respiration especially suffering. The sheep owner found the best treatment to consist in digging a small trench to accommodate the lower part of the body, and in the bottom of this holes for the front and hind feet, respectively. The sheep is thus maintained in an upright position, and its kicking and pawing against the earth appear to favor recovery. He was advised in future cases to use fifteen-minim doses of the tincture of nux vomica, repeating it twice at two-hour intervals, and afterward less frequently, as the symptoms required. The poisonous principle contained in the leaves of mountain laurel is andromedotoxin.—*The Druggist's Circular and Chemical Gazette.*

A FEW REMARKS ON DISEASES OF THE SKIN, WITH RELATION TO GENERAL AND SPECIAL THERAPY.*

By S. SHERWELL, M.D.,
BROOKLYN, N. Y.

CLINICAL PROFESSOR OF DERMATOLOGY, LONG ISLAND HOSPITAL MEDICAL COLLEGE; CONSULTANT PHYSICIAN, LONG ISLAND AND BROOKLYN HOSPITALS; MEMBER OF THE AMERICAN DERMATOLOGICAL ASSOCIATION AND THE NEW YORK DERMATOLOGICAL SOCIETY, ETC.

GENTLEMEN:—In the few minutes that I shall ask your patience, while endeavoring to outline the subject as above given, it will be evident that time will be afforded only for what appears to me to be practical suggestions: and these will be considered as addressed to fellow practitioners and colleagues, and not as to college under-graduates.

Surely when a man has been pegging away pretty much on a single line or subject for over thirty years, and has bestowed some honest work and thought on it, he may be allowed to have the courage of his conviction and opinion, in regard to what seems to him lacking or excessive in the treatment of skin diseases, by his colleagues, as aforesaid.

Firstly, then to consider general therapy of skin diseases it would seem to me that what is most evident and striking in my experience, is their excessive treatment by the ordinary medical man—"strenuous treatment," one might say.

The particular disease may have been correctly diagnosed by the medical man in attendance, and as to type, naturally and oftenest is found to be of the eczematous variety; it is then subjected very frequently to treatment of the fiercest, immediately on its recognition; this, too, as if it were an entity, alone entitled to consideration, and not a condition; and as one on which the general health has little or no bearing. Now, this is, in my opinion, generally not so; all conditions of the body, non-physiological in character, may, if not directly causative, be either predisposing or more remotely predisposing. Diathesis, any unhealthy condition of the body or bodily functions, or even of the mind, can be factors; and, as far as possible, these causes should be eliminated, or at least corrected, simultaneously or consecutively. I insist that this is frequently forgotten or neglected, or not acted on by the average general practitioner; sometimes even, I am sorry to say, by the more skilled specialist; though of late it is evident and a cause of satisfaction to myself and others how very much more attention has been given in practice to this point by special workers, and in the literature on the subject, as a glance at the text-books of to-day, and comparison with those of, say twenty years ago, will show very plainly. To say that a strumous or lymphatic child, or individual, a constipated person, or one rheumatically disposed (or indisposed to put it more exactly), or a psoriatic, or a diabetic, is not the more quickly relieved by appropriate constitutional treatment, is in my opinion a great mistake.

A slight course of hydrarg. c. creta or other alterative in the one, antilithic and purgative medicine in the other, appropriate diet and remedies in the third, or in all, will surely help appropriate topical treatment the sooner to a successful issue.

All this seems very trite, but to my mind needs insisting on, so often do I find it that my brethren call upon me for my assistance to relieve special conditions of the skin for which they have already used orthodox and proper treatment—often, as before said, too strenuously, but have neglected the quite "as weighty matters of the law," as of

---

* Read before the Associated Physicians of Long Island.

[illegible] eliminative, [illegible] and depurative in a general sense. That taken [illegible] as [illegible] the [illegible] and a number of kindred or allied conditions.

For one thing, and with all due respect to and to our enlightened, specializing, [illegible] of to-day, I have a great respect for the old practice of the old school physician of giving a purge in every case, and at the beginning of every treatment almost—to "open the skin and begin afresh," as it were—and as certainly and a [illegible] I believe in it in eczematic practice for the reasons I am about to give, certainly they will apply to the great North and West. To come down to this prosaic and yet delicate ground, how true it is as you know, that a farmer will in winter clear a way for his cattle to the water trough or the barn, to put [illegible], but it seems quite a secondary consideration for him to make the approaches and surroundings of the "[illegible]" used by his family equally convenient.

In this connection I would further add, that, to my mind, there is a great opportunity for some distinguished medical man or journal whose rank would place them beyond ridicule as to being faddist or clerical apostles or missionaries, in advocating this doctrine of physiological and ethical improvement in its application to the families and agricultural communities especially, and as said before especially of the North and West, where this evil, as far as my observation goes, particularly exists. Such a person or instrument might be of great benefit to the nation and save many from many evils—from insanity, up or down to an eczema.

It should not be so, but, I think, even in the cities, we see more clear-skinned and fresh-looking women than in various parts of the country districts, where there should be, and as a rule are, all the hygienic advantages except this one.

To come back to our proper topic, a large proportion of eczematous affections, especially of the acuter forms of that trouble, are by these judicious eliminative and depurative methods, in combination with the simplest and most innocent local alterative treatment, or even with simple protection alone, readily cured.

Another simple fact or element is, as I am convinced, true. We are taught by various authorities and some old precedents, not to use water or baths in these eczematous conditions, so that I frequently find on being called in consultation that the infant, child, or older individual is absolutely rancid and stinking for want of detergents or ablutions. This is, in my opinion, all wrong.

True, I believe that a soaking with water for any length of time, so as to macerate the epiderm, and to bring into play the osmotic action of the skin, is improper; but that effete matter and secretions should be removed once a day at least, in almost if not every case, is with me an axiom.

A light and cleansing application of soap and water, possibly an inunction of olive or sweet almond oil having preceded it, is beneficial and as esthetic as beneficial. The oil in these cases making in your own hands an "uber-fettete" soap, as the Germans call it. This is a simple matter, gentlemen, but important, comforting to the patient, and desirable in every sense. This is particularly useful and necessary when unguents have been applied, and butyric acid decomposition has necessarily followed from the heat of surface. Sometimes in the cases in which lotions have been used, a wiping off with a warm wet cloth will suffice.

While in an eczematous frame of mind, I would say that, in the immediately foregoing remarks I have considered here especially the eczemas of infantile and tender-skinned young people and adults. There is however a chronic variety common to robust and usually elderly people which, I take it, but few among you have not seen and been bothered with, and you will recognize the type. It occurs in robust males of the class mentioned, as a rule. The lesions thereof are horny, pseudo-psoriatic, slightly scaly, indurated patches situate very frequently on one or both legs about the ankles, sometimes extending up the leg four or five inches or more, but with no ulceration. The individual is well nourished, healthy, possibly and usually of rheumatic type, though equally possibly never in his life having had an acute attack or anything but slight manifestations. The urine is relatively scanty, often high colored. He is a man of rapid ingestion of food, and though not an invalid of poor or imperfect digestion. He just feeds his stove with furnace coal, leaving a plentiful deposit of ashes and clinkers, which he neglects to take down regularly and properly. There's your analogue, gentlemen.

Such a one will bear depletment and depurative treatment well, and often, shall I say almost always, antirheumatic treatment for a while, as Epsom salts, colchicum, or the salicylates and alkalies, with great benefit, in combination with a more stimulative local treatment. You need not be afraid to wash, aye, and even rub with tincture of green soap, or like detergent, thereafter applying, in the interval, more or less modified ungt. hydrarg. ammoniat., the tarry oils, salicylic acid, resorcin, and what not.

It is hard work to generalize treatment, here you see in this frank talk, I have already come down to considering a special form, so I will go back to recapitulation of what I earlier asserted, that no skin disease can or should be treated as a separate entity; the individual before all.

Most drugs and medicaments used in dermatological therapy have been abused in using, from sulphur up or down to arsenic, and all may be said to be good when used with judgment, but, like the artist's colors, they have to be mixed with brains, as part of the ingredients.

One will even find authors pleading against the use of arsenic, a drug which in its way and appropriate place, is one of the most beneficent of remedies.

There are few weeks, I was going to say days, in which cases are not brought to me, or occur in my practice, in which arsenic in the form usually of Fowler's solution (one of the best preparations of the drug it may here be said) has not been injudiciously or excessively used. We all know how Hunt of England used it internally, externally, eternally, and for all things, but, used judiciously, and generally in small doses, in strumous, lymphatic and cachectic children and in combination with the iodide of iron, also in small dose, I believe it to be the best tonic that can be used in such cases, with that and mild fractional doses of hydrarg. c. creta or even calomel, often nothing else but protection to the skin, you will find cases rapidly recover, and the general health return.

The above has no reference to lues or syphilitic affections, which naturally would receive their proper care and special treatment.

Again people from malarial districts of whatever age, can almost certainly be benefited both constitutionally and locally by the use of arsenic. One must also be blind or bigoted to deny its action, though not always mathematically regular, in diseases of the epiderm and upper layers of the corium. The crime of its use or abuse consists in giving it in all skin diseases, especially those of an inflammatory and easily-irritated type, as, for instance, acnes, rosaceas, etc., and expecting it to do good. As to special or particular local remedies for the diseases under consideration, a few words: I have, in various monographs, given as my opinion that almost all pharmacopeial preparations for topical use are too strong. I mean by this, of course, not for individual cases, but as a general proposition.

I would, in this sense, say that, even about that bland and mildly stimulative application, the oxide of zinc ointment, used, as I frequently see it, on the soft and weeping skin of a babe; or on the tender flexor surfaces of older individuals, or on a sensitive erythematous surface. It is too strong; it is better far to soften it with a certain percentage of a more lenitive ointment, such as cold cream or fresh lard. Often, too, this ointment has been kept a long time in pharmacies, and has become more or less rancid in spite of the benzoic addition. It is always better to write for your own compounds, taking care at least that they are gentle enough; it is better and far easier to advance in strength than to recede. The faults of excessive strength are most manifested in the official mercurial ointments; they are intended for the average (or as near that as may be) adults, they should not be used without discrimination, but nearly all should be modified as above. Especially is this true in regard to the unguentum hydrargri nitratis.

Time is too short, and the list too long, to further particularize. I would like, however, to mention and deprecate the use of one non-official drug, that is to say, in excess. I refer to chrysophanic acid or chrysarobin, an active remedy, and one very efficient, used rightly, but sometimes used with great recklessness. I would like to say that the cases in which I apply this in unguent form, bearing a strength of over 2 per cent., are excessively rare. Skins differ; the brunette skin is ordinarily of a tougher and more resistant type than the blonde, and the strength may be increased in the former, but even then rarely.

For most of the diseases in which this remedy is found so useful, as in psoriasis, and eczemas of the type that simulate psoriasis, etc., ½ per cent. to 1 per cent. is ordinarily strong enough; to increase its penetrative or more efficient action, a small amount of salicylic acid, with a little alcohol, about the same amount, may be rubbed up with it.

I think it is ordinarily believed that vaselin and glycerin are always and under any circumstances soothing to the skin. That is far from being a fact. I believe that the first named (even when of the purest quality) is more or less of an irritant to 10 per cent. of the community. I use it only as a base for stimulant unguents, or when its non-rancidifying qualities are especially desirable.

As to glycerin used in its purity, while some bear it with apparent impunity, other skins do not. I think it injudicious so to use it, on account of its extreme affinity for the water of the tissues; it has the tendency to excite osmosis, and while it is apparently a smoother of, and lenitive to the skin, I believe it tends to make it harsher and more irritable in the long run.

No one would think it very soothing on applying it to the abraded surface, and seeing the serous flux that ensues therefrom.

The same may be said of many alcoholic preparations, as bay rum, etc., used freely on sensitive skins they at first appear to do good, but often when used in full strength and continuously they are liable to cause irritation of serious character in some individuals. . . . .

There are a number of these minor dermatological points on which I should have liked to have freed my mind, and, since I am permitted, will mention briefly one or two which now occur to me as happening not infrequently in my consultation practice, and which I think should not so do.

The first, an important and grave one, both to the individual patient as well as to the family physician, is, for example, a patient brought to me, who often is apparently a fairly well-nourished and, even, florid person, ordinarily of mature age, perhaps even further advanced, who has a history of a series of phlegmonous eruptions, either furuncular or more distinctly and seriously carbuncular in character, occurring by preference regionally; as, for instance, on nucha or gluteal region, or lower limbs, persistent, and the region of election, as before said, often well defined. I always think of diabetes in this class of cases, and have the urine carefully examined for sugar and that not alone of one sample of the urine, taken, as is the usual rule, in the morning on rising, but a sample of all that voided during the day, or even, preferably, of that voided at night, the heaviest meal of the day having been taken just a few hours before that time; this commonly shows a more distinct reaction than that of the urine of fasting, micturition possibly having occurred once or twice during the night. The skin trouble is often, in my opinion, one of the first noticeable symptoms of the diabetic diathesis, and just the state of things pointed out should always excite suspicion. Naturally it would be a work of supererogation for me to take up your time considering treatment of this class of cases, it suggests itself.

Another and more simple affair often causes annoyance and trouble to the physician and family respectively, is so common and matter-of-fact that I almost hesitate to speak of it, did it not occur so often. A patient, a child usually, and oftenest a girl, has an obstinate so-called eczema of the nucha and occipital region, is brought for treatment.

Now, as a matter of fact, I think nine-tenths of these irritative eczemas of the nucha and thereabouts are due to the present or past work of pediculi, though they may have been so few in number as to have escaped observation, or the family so ultra respectable, and the child so well cared for, that the thought of their presence, to the house-mother or nurse, would seem like a sacrilege. Ordinarily, however, on a careful examination just below the occipital ridge a few discouraged-looking pediculi, or on the shafts of the hairs a few of their ova, or nits, will be found. The zinc or other unguent which has been prescribed by the family medical man for the relief of the condition has, as before said, not done the insects any good, but, to use a sporting simile, "though somewhat disfigured, they are still in the ring," to the annoyance of the family, and sometimes to the discredit and mortification of the family physician. These things I have seen when a mild antiparasitical ointment would have quickly cleared up matters.

The Yale Medical Course.—The announcement has been made that hereafter a student in the academic department at Yale University who intends to take up medicine can so arrange his studies in the last three years of his academic course as to cover the work required in the first year in the medical school, thus shortening the time actually spent in the latter to three years.

A CASE OF OTITIC BRAIN ABSCESS AND THE LESSONS WHICH IT OBVIOUSLY TEACHES.*

By ROBERT LEWIS, Jr., M.D.
NEW YORK

ASSISTANT SURGEON, NEW YORK EYE AND EAR INFIRMARY; INSTRUCTOR IN OTOLOGY, MEDICAL DEPARTMENT, COLUMBIA UNIVERSITY

This patient, R. C., the history of whose ear and brain disease I have the honor to present for your consideration, was admitted to the New York Eye and Ear Infirmary, in the service of Dr. Gorham Bacon, on the twenty-third day of January, 1901. From her and from her friends the following history was obtained. Since her childhood (the patient is now twenty-three years of age) she has had an almost constant purulent discharge from her left ear. This discharge has, at times, been thick and foul-smelling, and has contained small, granular masses, doubtless of cholesteatomatous character. Ten months ago, at a time when the discharge had apparently ceased, she complained of pain in the ear. An ice-coil was applied by her physician and the pain subsided. At the same time the discharge reappeared. On several subsequent occasions she complained of headache, which was of a general character and not located at any particular point.

The attack which caused her to visit the Infirmary for relief began on Sunday, January 13, with a cold. On January 14 the discharge ceased, but she had some pain and tinnitus in the affected ear, as well as headache on the same side of the head. There was no dizziness nor nausea. The patient continued to grow steadily worse, and on Thursday, January 17, complained for the first time of chilly sensations and of pain in her back. Her medical attendant made the diagnosis of "grippe."

On January 18 the patient had a severe chill, which lasted twenty minutes; her teeth chattered and she shook convulsively. Temperature rose to 104° F., but was not followed by any perceptible perspiration. The pain in the left side of the head became severe and extended down the side of the neck, the mobility of the latter was normal. The lower extremities were rigid. Some vomiting occurred, but it was not of a projectile character.

On Saturday, January 19, at 1 P. M., the patient had a chill lasting eight minutes, which was followed by a rise of temperature and sweating, with much exhaustion. At 7 P. M. she had a second chill, which lasted twenty minutes.

January 20. Another severe chill lasting twenty minutes. This was followed by fever and sweating, muttering delirium, and a tendency to drowsiness. Previous to this time her mind had always been perfectly clear.

On January 22 a slight left facial paralysis was noticed. No chill occurred on this day, but the patient was very weak. Amnesic aphasia also appeared on this day for the first time. The drowsiness continued.

On January 23 the patient was admitted to the Infirmary and I saw her for the first time. A physical examination showed the left mastoid to be slightly tender over the antrum and tip, and over the opening for the emissary vein. There was no œdema over the mastoid. The external auditory canal contained an abundance of foul discharge. On the posterior wall of the cartilaginous portion there was a circumscribed area of inflammation. There was no tenderness in the neck, nor did the jugular vein seem to be thrombosed. No ocular paralyses; no optic neuritis, no motor paralyses. The retinal veins of both eyes were paler than usual. There was slight general anesthesia, but with no difference between the two sides. The knee-jerk was normal. The patient complained of being unable to keep her eyes open, and she answered questions very slowly, although rationally. The amnesic aphasia was marked. She used the word "fan" indiscriminately, spoke of her physician as "Dr. Fan," asked for her "fan" when she meant her [illegible], etc. She realized that she used the wrong word and manifested annoyance over what she called her stupidity in making such mistakes. She could not name the objects which were held before her, but she would correctly state the purpose for which each was used. Thus, for example, while she seemed unable to call a key by its proper name, she stated correctly that it was something used for locking and unlocking a door, a pencil something to write with, a watch something to tell time by. The only exception was with money, the denomination of which she appeared to have no difficulty in correctly recognizing. The temperature was 103.6° F., the pulse 108, and the rate of respiration 24.

A diagnosis of mastoiditis and brain abscess was made, and it was believed that the latter would be found situated in the temporo-sphenoidal lobe and involving the third and ascending frontal convolutions.

Operation.—The patient was prepared in the usual manner, and a curvilinear incision behind the auricle was made and was extended forward in such a manner as to expose the entire squamous plate of the temporal bone. Another incision was carried upward from the summit of the curvilinear incision toward the vertex of the skull, and a third incision backward from a point opposite the external auditory canal. The mastoid vertex was found to be normal in appearance and of ivory-like hardness. When the antrum was opened a very foul-smelling discharge appeared, and the cavity itself, which was very large, was found to be filled with cholesteatomatous material. Bone necrosis extended downward to the tip and sufficiently far backward to involve the wall of the sigmoid sinus. I exposed the latter for a distance of about one inch and found it to be covered with a foul-smelling pus and with granulations. The pus kept oozing out from the region near the antrum, and, on exploration with a probe, there was found a fistulous opening that led from the tegmen tympani for some distance into the cranial cavity. On the removal of the tegmen a tablespoonful of foul-smelling pus flowed out. The posterior upper wall of the external auditory canal was removed, the tympanic cavity was thoroughly curetted, and all granulations and remnants of necrotic ossicles were removed. The greater part of the squamous portion of the temporal bone, together with some of the anterior border of the parietal bone, was removed. The exposed dura was blackish in spots, and everywhere covered with lymph or bathed in pus. This extradural abscess was situated fairly far forward and was spread out over that part of the dura which covered the temporo-sphenoidal lobe. At the same time it was walled off, by adhesive inflammation, from the healthy dura. It was at this point, where the tension of the dura was greater than normal, that I made an incision into the brain to a depth of about three-quarters of an inch in an upward and forward direction. The incision afforded escape to some disintegrated brain material and pus. Exploration revealed the fact that the abscess cavity was about the size of a large walnut and was lined with a distinct membrane.

Syringing was not resorted to, but instead the cavity was wiped out with pledgets of gauze. An annoying hemorrhage occurred from one of the meningeal vessels. Sterile gauze packing was used. Sutures were employed for closing the upper portion of the wound. Firm pressure, by means of dressings and bandages, was applied. The operation lasted one hour and fifteen minutes, and was followed by little or no shock. The temperature after the operation was 98.4°F; pulse 100 and of good volume and strength. During convalescence the temperature never went above 100°F., nor below 98°F. For a period of about one week following the operation the patient was restless and, at times, nauseated, and she suffered somewhat from retention of urine.

---

*Read before the Medical Society of the State of New York, at its semi-annual meeting in New York City.

On January 26 the facial paralysis was found to be scarcely discernible. The aphasia had grown somewhat less noticeable, but the patient still complained of much headache. When the wound was dressed, no irrigation was used; the cavity was simply wiped out with cotton pledgets soaked in a weak bichloride solution, and the wound was then packed with sterile gauze. The wound was dressed every other day.

On February 20 it was found that the aphasia had entirely disappeared.

On March 7 a small abscess developed in the anterior extremity of the wound. The patient was etherized, and an incision was made over the point of fluctuation. A discharge of pus followed, and, on probing, a small point of necrosed bone was found. This was removed with a rongeur and curette. The patient was discharged from the hospital on March 21.

By the middle of April, twelve weeks after the operation, epidermization of the tympanic cavity had taken place, and the external wound had entirely healed. The patient's general physical condition, as she declared, had never been better.

My chief object in reporting the history of the present case is, not so much that I may furnish a fresh illustration of the successful results which are obtainable from fearless, yet rational, surgical skill, as that I may draw attention to and emphasize the fact that the organ of hearing receives far less consideration at the hands of the medical practitioner than does that of the hardly more important organ of sight. It seems to me that it would be scarcely possible to find a more striking example of the dangerous and destructive complications that may arise from neglect of the proper treatment of a chronic purulent inflammation of the middle ear, than that which is afforded by the case of which I have here, very briefly, given the history. And in this connection I beg to make the following quotation from that classical work on "Diseases of the Brain and Spinal Cord," by Dr. William MacEwen:

"When the tympanic cavity has become the seat of chronic suppuration, with ulceration of the mucous membrane extending into the antrum and mastoid cells, it becomes a standing menace to the safety of the patient.

"The disease progresses insidiously, and one cannot be certain as to when and where it may end. A person might as well have a charge of dynamite in the mastoid antrum and cells, as one cannot know the moment when accidental circumstances may arise which may cause the infective matter to become widely disseminated all over the cerebrospinal system. Chronic otorrhœa is much too lightly regarded, and is frequently considered as a mere inconvenience, instead of a menace to life. It is true that many affected with chronic purulent otitis media pass through a long life without suffering obtrusively from it, and may die from causes neither directly nor indirectly associated with it. On the other hand, the disease is one which advances insidiously, often without pain, until very extensive destruction of the middle ear and the mastoid antrum and cells, with thinning of their osseous walls, and serious invasion of the meninges, the blood vessels and the brain itself, occurs. The mere localized suppuration, continuing for many years, is a source of weakness, tending to waxy or amyloid degeneration of the tissues. As long as the middle ear and its recesses are the seat of pus secretion, they are liable to become a focus for pathogenic organisms, which may find their way into the general circulation, or by extension invade the meninges and brain. From this very small focus the brain and cerebro-spinal meninges may become affected. One who had a chronic purulent otitis media is liable to have, with very little warning, a most serious or even fatal illness. Besides those who succumb to such diseases recognized during life, others do so from disease directly or indirectly the result of chronic otitis media and its extensions, but which are registered under the heading of its prominent sequelæ—pneumonia, pleurisy, meningitis, etc.

"It is a fact that the records of most aural hospitals show that their patients are all confined to the earlier decades of life. This may be variously interpreted, but it is probable that many people die from such sequelæ before they reach forty years. Under these circumstances all persistent purulent discharges from the middle ear ought to be regarded seriously, and the medical attendant ought not to rest satisfied until the discharge is cured. If this cannot be accomplished after sufficient trial by the ordinary means at the disposal of the aurist, applied through the external auditory meatus or Eustachian tube, then recourse ought to be had to operative treatment, directed first to arresting encroachments of the disease toward the cerebral and cerebellar fossæ; secondly, to opening the various recesses of the mastoid process and removing therefrom diseased membrane, granulation masses, cholesteatomatous débris and bone erosions contained therein; thirdly, to affording a free outlet to discharges which are otherwise pent up; and fourthly, to filling up these parts with fresh, fibrous tissue, or to forming a permanent opening to the middle ear through the antrum."

These cases, of which Dr. MacEwen speaks, ought seldom to occur. The simple fact of the occurrence of the disease *generally* means culpable neglect of an acute otitis media, for, if proper therapeutic measures are carried out in these primary inflammations, a secondary or chronic form of the disease will not follow. Of course, grave complications, such as mastoiditis, acute cerebral and cerebellar abscesses, and septic sinus thrombosis, may occur in the course of an acute inflammation of the middle ear, for the development of any of these complications is at times perfectly unavoidable, and may take place under the most careful and skilful treatment. When they develop, however, as a complication of the chronic form of purulent inflammation of the middle ear, their occurrence can no longer be termed "unavoidable." They should have been prevented. And this suggests the question, How may we prevent the acute form from lapsing into the chronic form, and, to go still further back, how may we prevent many cases of the acute disease from arising?

Nearly all disease of the middle ear has its origin in some pathological change in the nares or nasopharynx, through extension along the Eustachian tube or along the lymph channels of this tract. So here is the first point of attack. We should not let [illegible] without treatment.

Among the various causal affections, the one which plays the most important part in producing inflammation of the middle ear, especially in childhood, is indisputably hypertrophy of the pharyngeal tonsil. Owing to this fact, I feel warranted in saying that every child born into the world should be examined a number of times, during its early life, for this hypertrophied condition, and when it is found to exist, either alone or associated with hypertrophy of the faucial tonsils, as is frequently the case, the mass should be removed, as should also the hypertrophied faucial tonsils. Children who have such a growth of adenoid tissue are much more prone than other children to contracting the exanthemata, tonsillitis, diphtheria, acute coryza, etc., catarrhal processes which are accompanied by a purulent secretion in the nares or naso-pharynx. It is an easy and short passage for the bacteria to make their way from this point along the Eustachian tube to the middle ear, where, owing to the rigid surroundings of this small cavity, they may do much damage.

Again, if acute otitis media does arise in the presence of this growth in the vault of the pharynx, it is much more difficult to treat the attack successfully, for the mechanical obstruction presented by the latter interferes most seriously with the reestablishment of natural drainage, and thus favors the development of chronic conditions in the middle ear. The mechanical interference referred to is brought about by this growth in two ways: first, by pressing on the pharyngeal opening of the Eustachian tube, and, secondly, by the participation of the tubal mucous membrane in the same phenomena of congestion and swelling which are taking place in the enlarged tonsil.

To recapitulate, it is the physician's first duty to properly care for the pharyngeal and nasal cavities of his patients, especially children, for by the adoption of this course he will materially diminish the frequency of attacks of acute otitis media. Secondly, he ought never to neglect a case of acute otitis media, but should, at an early stage, freely incise the membrana tympani in order to secure good drainage, and should effectively cleanse the parts at short intervals. Absolute rest should be enjoined, and the intestinal tract should be kept freely open. It is by these measures, in the main, that we may expect to effect a cure. But if, after the lapse of a reasonable length of time (not more than four weeks at the longest), it is found that the inflammation still persists, the case should be put into the hands of an expert, and not allowed to drift into a chronic condition, as it almost surely will if the criminally ignorant statement is made to the patient that he "will outgrow it in time."

Finally, it should be made plain to the patient who is affected with a chronic discharge from the ear, that such a discharge points, in the majority of cases, to the existence of a diseased process in some part of the middle ear, and that the ultimate issue of this process is oftentimes death. On the other hand, there has been accumulated during the past decade a mass of evidence which makes it no idle boast for the specialist to claim that nearly every one of these cases is curable—in some instances by skilful local measures, and in a still larger number by a suitable surgical operation.

A Leper Reservation in the Philippines.—An uninhabited island about two miles long by one mile wide, well watered, and lying north of Luzon, has been selected as a place for a Philippine Leper Colony. The name of the place is Barri Island.

APPARENT CURE OF MALIGNANT ULCER OF BREAST AFTER OOPHORECTOMY.

By WM. P. [illegible], M.D.,

[illegible]

Mrs. A. B., between forty and forty-five years old, married, never pregnant, had always suffered from dysmenorrhea. She noticed in the early summer of 1897 a hardening of the left breast; the disease slowly progressed, and after a year, during which time the nipple retracted and the induration increased, an external ulcer formed. This ulcer persisted, and when I first saw her in April, 1900, measured about two and one-half by one and one-half inches in area. There was an extensive and very hard induration surrounding the ulcer, all the tissues being matted solidly together and firmly adherent to the chest wall, which formed the floor of the ulcer; the surface of the ulcer was gangrenous with a profuse fetid discharge.

Although no involvement of the axillary glands could be felt, in view of the depth of the ulcer and the infiltration of the surrounding parts, I thought operation was not advisable, and so informed the patient's husband. He requested me to use a mode of treatment, which consists of the injection into the tissues surrounding the growth of a thickish phenol-smelling liquid, which is sold for thirty dollars a bottle of about two ounces. This treatment is supposed to cure cancer, and a formidable list of favorable reports has been made. The treatment was persisted in for about a year, during which time the disease steadily progressed, when it was discontinued, and the operation of oophorectomy was advised, I having heard of the success which sometimes follows that procedure.

The operation was done September 30, 1901. On that date the ulcer measured about four and one-half by about three and one-half inches, occupying the site of the left breast which had been destroyed; its edges were indurated, elevated, undermined; its floor was the chest wall; its surface was in places gangrenous, with a profuse purulent, stinking discharge. No marked involvement of axillary glands could be felt. The ulcer had at this time been progressively enlarging for about three and a half years. The ability to use the left arm was very much impaired. Below the lower border of the ulcer, and about one inch distant, were two nodules about as big as filberts, dark red, very hard, firmly attached, apparently, to the chest wall. The ulcer had been kept covered with a simple dressing of vaselin, which dressing alone was used after the operation.

At the operation the ovaries were found small, prolapsed, very fragile, and densely adherent, with a troublesome adhesion of the left ovary to the sigmoid flexure, which necessitated considerable deep suturing to control bleeding. There was no marked evidence of salpyngitis on either side.

Recovery was quite uneventful, the dressing being removed on the tenth day. The wound was found perfectly united and the patient was up in three weeks. In just eleven weeks from the date of the operation the ulcer was completely healed, being covered with a firm, smooth, dry scar, which condition still continues. The two nodules in the skin are now smaller, softer, freely movable, and apparently undergoing absorption. The function of the left arm is almost completely restored.

Granulation was first observed about four weeks after the operation, and from that time the healing process went on rapidly. It was especially interesting to watch the filling up of the deep excavations, one of which would have held more than a drachm of pus, and the flattening down of the elevated indurated edges. No portion of the growth was excised for examination, the clinical evidence being considered quite sufficient to establish the diagnosis of scirrhous carcinoma.

Some Newer Aspects of Heredity in Tuberculosis and the Sanatorium Treatment.—E. R. Baldwin calls attention to the fact that patients may inherit a certain weak place in the body, as, for instance, in the lung, so that the disease in the child breaks out in the same place as in the parent. Certain statistics of patients under his own observation reveal the following facts: About sixty-three families containing one hundred and sixty-six tuberculous persons, 70 per cent. first developed the disease in the corresponding lung. Ninety-four of these patients came under his observation. In the remainder, the history was obtained from their relatives. In twenty-eight families where parental tuberculosis existed, 78 per cent. had children with corresponding disease. In one family the father and four children had the same lung first affected. In thirty-five families with one or more tuberculous brothers or sisters (parents not affected) 63 per cent. had corresponding disease. These proportions are large enough to suggest, incidentally, a practical point in diagnosis. The family physician knowing the location of the disease in one member of a family should be alert in seeking for signs in the corresponding lung of others in the same family. Again, it has long been known that small hearts were characteristic of tuberculous individuals, and this also may be an inherited condition. It is probable that the inheritance of vulnerability in a point of least resistance in the lungs belongs to the same category. The fact that the inherited characteristics are not necessarily the product of tuberculous disease in the parent, of course, does not contradict the observation that where the mother suffers from tuberculosis before the birth of offspring, the infants will probably have a very weak constitution as a direct result of the poisons produced in the tissues of the mother. It is not so clear that this occurs in the case of the father, but such children die of marasmus or of indefinite diseases, and usually survive but a short time. If, however, the tuberculous mother has no acute symptoms, and has good nutrition, there are many instances of very healthy children being produced, and were it not for the presence of infection after their birth, more might grow to strong maturity.—*Yale Medical Journal.*

A Contribution to the Study of Amæbic Dysentery in Children.—Samuel Amberg quotes the comments of Harris as to the relative occurrence of this disease in children and adults, as being about ten persons above to one under twenty years of age. There seem to be only about half a dozen cases on record under ten years of age. In the five cases reported in this paper, two were members of the same family exposed to the same influences, and two others were playmates living in close neighborhood, and drinking from the same contaminated sources. A third child of their company was also taken sick with the same symptoms, and probably suffered from the same disease; but the writer was unable to secure control of the case. The clinical type to which these cases belong is that of moderate intensity. There is almost no fever or acceleration of pulse. The number of stools varies from two to six in twenty-four hours. One of these cases, however, was of a more severe type. In these mild cases it is rather surprising to note the small amount of discomfort that the children suffer. In two cases there occurred a prolapsus recti. In none of the cases was any sign of affection of the liver. Abscess of the liver seems to be of very rare occurrence in children. The reaction of the fæces was mostly alkaline. The odor of these was always very offensive. The diagnosis was based upon the finding of motile amœbæ containing red blood corpuscles. The Charcot-Leyden crystals were present in the fæces of all but one case. The number of neutrophile elements in the passages was mostly very small. They seemed mostly to be less numerous than the eosinophile elements. In four of the cases there was a varying degree of anæmia. The number of blood examinations in these cases was not sufficiently numerous to allow definite conclusions.—*Bulletin of the Johns Hopkins Hospital.*

What Bearing Have Skin Diseases upon Longevity?—Charles Warrene Allen says that the most important class of cases for consideration is that including the tuberculides, syphilides, leprides, diabetides, and scrofulides. Subjects of tuberculous cutis and lupus vulgaris cannot be regarded as free from danger of grave internal tuberculosis. Of themselves these constitute grave diseases not without danger to life. As to lues, while the individual who has been properly treated may live as long as one never infected, still, as a class, those who have once had lues do not make the best risks. Leprosy in its early stages is difficult of recognition, and as the period of latency is extremely long, a leper may secure insurance while he himself is still ignorant of his impending fate. Diabetides are of extreme importance as indicating the underlying grave glycosuric state. Scrofulides form an indistinct class, but strumous subjects with ulcerations, lymph nodes or lichen scrofulosorum cannot be considered as gilt-edged risks. On the whole, skin eruptions have a very decided bearing upon life prospects, and should receive more consideration and attention from all branches of the profession than they have done in the past.—*The Medical Examiner and Practitioner.*

Plague in India.—The plague figures in India have again risen, and the epidemic is now more widely distributed than ever, and in the majority of the provinces it is steadily increasing. The recrudescence in Bombay City is unmistakable, and Poona City is in the throes of another severe outbreak. There are also signs of development in Calcutta, and the quarter of the city hitherto first affected is returning more cases. For 1901, up to the end of November last, the official returns for the whole of India give 307,000 seizures and 233,000 deaths, and up to December 14, Bengal had 90,000 seizures and 78,000 deaths, as compared with figures of less than half these for the previous year. This shows the generally unrecognized increase of the epidemic during the past year. —*Lancet's Indian Correspondent.*

Potassium Permanganate.—It can ignite glycerin or alcohol and detonates when rubbed up with confect. rosæ. An unlucky apothecary attempted to dispense the following:

Pot. permangan. and alcohol, āā 10 parts; distilled water, 15 parts.

Scarcely had the bottle been corked when an explosion took place, and the boiling liquid spurted into the face of the surprised pharmacist. He nearly lost the sight of one eye, and was disabled from work for more than a month.
—Walter G. Smith *in The Practitioner.*

White Illiteracy in the South.—The census reports have revealed that the number of illiterates in the South is very large. The *Atlanta Constitution* commenting on this says:

"There is no more humiliating fact that an intelligent Southern man has to face than this: that among the white people of the South we have as many illiterate men over twenty-one years of age as we had fifty-two years ago, when the census of 1850 was taken."

The Salt Pack in Rheumatic Gout.—Mr. Jonathan Hutchinson says, in the January *Polyclinic,* that he knows of no remedy so effectual in getting rid of irritation and synovial effusion in connection with rheumatic gout than the salt pack. This consists of flannel soaked in a saturated brine of common salt, which is wrapped round the affected joint, covered with oiled silk and a bandage, and kept on the whole night. It should be applied every night until the cure is effected.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published by

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 15, 1902.

A UNIFORM SYSTEM FOR THE REGISTRATION OF DEATHS AND THE COLLECTION OF MORTALITY STATISTICS.

The need of uniformity in the law regulating registration of deaths and the collection of mortality statistics is obvious. No accurate statistics of mortality can be gathered unless the methods in vogue for this purpose be uniform throughout the country. At the present time the law governing these matters differs in points of detail in various States, while some cities and States are non-registration areas.

The Census Office of the United States has made, for some time, efforts to remedy this state of affairs—and with a degree of success—but there still remains the greater part of the work to be accomplished ere complete order be evolved out of partial chaos.

The Committee on Demography and Statistics in their Sanitary Relation to the American Public Health Association, at their recent meeting, decided to take up the subject, and thereupon the Census Office determined that its wisest course would be to coöperate with this body.

The Committee has published a paper in which is set forth its conclusions as to the essential requirements of a law for the registration of deaths and the collection of mortality statistics.

An epitome of these provisions are as follows:

1. Deaths must be registered immediately after their occurrence.

2. Certificates of death should be required.

3. Burial or removal permits are essential to the enforcement of the law.

4. Efficient local registrars are necessary.

5. The responsibility for reporting deaths to the local registrar should be fixed.

6. The Central Registration Office should have full control of the local machinery, and its rules should have the effect of law.

7. The transmission and preservation of records should be provided for.

8. Penalties should be provided.

These provisions seem to cover the whole ground so far as is feasible under existing conditions, but as the Committee state, "It is not practicable to draft a complete law that can be adopted without modification, in the States or cities which may wish to enact such legislation. The paper must, therefore, be considered as furnishing the accepted view of the general scheme for registration, and as affording interested parties an authoritative basis for constructing a law adapted to local conditions. The Committee further declare that it is desirable that Congress, the United States Census Office, the medical departments of the Government, the legislatures of all the States, their boards of health and registration bureaus, municipal boards of health, and all sanitary, medical, statistical, and economic associations should unite in efforts to extend to this country the practice of accurate registration of deaths and the publication and utilization of the mortality data resulting therefrom."

To bring about this most-to-be-desired end, a thorough reform must be effected in the careless methods now practised.

The United States stands almost alone among the civilized nations of the world in that she has no national uniform system of registration and enumeration. It is impossible for her census officers to collect data as to the movement of population and other facts which are extremely valuable considered from every standpoint.

Registration has been left in the hands of separate and independent States and has been done well or ill or left undone, in accordance with the will of each State, and with no reference to the utility of registration as regarded from the broader point of view of the Federal Government.

An alteration of this condition of things upon the lines suggested by the Committee of the American Public Health Association, endorsed by the Census Office and the Commissioner of Labor, would have the effect of rendering available most valuable statistical information.

The question of a national uniformity of systems will be brought by the Director of the Census to the immediate attention of the Governors and Legislatures of the non-registration States, and every effort will be made to procure the introduction and passage of the desired laws.

The movement is one in praise of which it would be impossible to say too much. Therefore it is to be hoped that medical men in all parts of the country will use their utmost endeavors to bring to pass a uniform and efficient system of registration throughout the United States.

FOREIGN BODIES ACCIDENTALLY LEFT IN THE ABDOMINAL CAVITY.

DR. August Schachner, Professor of Surgery in the Louisville Medical College, read before the Louisville Surgical Society on June 10 a paper on this subject, in which he points out that no matter how careful an operator may be such accidents are on occasions unavoidable, and records numerous examples in support of this statement, procured from many surgeons whose opportunities for observation in abdominal surgery were known to be large. In addition, he gives a list of 101 cases contributed by Franz Neugebauer to the *Monatsschrift für Geburt und Gynakol.* The conclusions come to by Dr. Schachner are as follows:

1. So long as surgery continues an art, so long will foreign substances continue to be unintentionally left in the abdominal cavity.

2. That the recorded cases are not representative of the true frequency of this accident.

3. If the foreign body is of an aseptic character, nature endeavors to care for the same by encapsulating the foreign substance primarily in a fibrous exudate interspersed with leucocytes, and second-

arily enclosing it by the contraction of adhesions between the different abdominal viscera, or the viscera and abdominal wall.

4. In the spontaneous expulsion of a foreign body from the abdominal cavity nature seeks exit through points of least resistance, which are either the alimentary tract or an imperfectly united wound, or less frequently through the reopening of an apparently well-organized cicatrix.

5. A foreign substance may remain quiescent for years in the abdominal cavity.

6. The disturbance which a foreign body creates in the abdominal cavity depends upon its sterility, size, character, *e. g.* regularity of outline and presence of sharp or pointed surfaces; density, point of location, individual tolerance of the peritoneum, and behavior of the individual.

7. The symptoms of a foreign body in the abdominal cavity may vary from nil to that of the most violent abdominal disturbance.

8 The symptoms not infrequently suggest a low and protracted form of sepsis or an ileus.

9. Unexpected circumstances, unusual complications, and diverted attention explain many of these accidents.

10. While the counting and recounting of sponges and pads before and after an operation should and always will be a most important feature in the prevention of this accident, yet the cases are numerous where the accident occurred notwithstanding this count by one and even two nurses or assistants.

11. The plan of attaching tapes or threads to pads and instruments has received the recommendation of many operators, but the fallibility of this is as clearly proven as is the former.

12. In restricting ourselves to the smallest number of pads, sponges, and instruments, we adopt a system of simplicity that must appeal to all as one of the most important elements in the avoidance of this accident.

13. We can only hope to reduce these accidents by the observance of the highest degree of simplicity, system, and watchfulness.

14. If the surgeon at the close of the operation asks for a count of sponges, and this is made, and an assurance given that all sponges and pads are present, his responsibility upon this point ceases; for it is neither prudent nor fair that he should leave his, the most important part, to do duty that justly belongs to the nurse.

15. The real factors in the avoidance of this accident are the recognition of system, simplicity, and watchfulness to the most exacting degree.

16. At the bottom of most of these accidents, we find a diverted attention, a defective system, or a dangerous degree of complexity.

17. We are obliged to conclude that to a certain extent the surgeon is responsible for things about the operation, and after that the responsibility must rest elsewhere.

18. No hard and fast rules can be made regulating the responsibility in every case, but each will be required to be decided upon its own merits, and the responsibility be fixed accordingly.

19. There are risks that the patient must assume and that cannot rightly be transferred to the operator (Sanger of Leipzig).

20. In other vocations it is reasonable to assume that, unless properly prepared, one should not act; but in surgery one is occasionally compelled to act, even though it is known that he is not prepared; and in these conditions to adopt any other course than that it would be attended with the loss of more lives than if we did not make the best of circumstances.

Dr. Schachner has dwelt with the subject exhaustively, and his conclusions are fair and just. The main point in an abdominal operation, is to the greatest care compatible with needful celerity, and to use the simplest methods possible.

The placing of responsibility as a very difficult question to decide; in fact, virtually impossible; so that it may be taken that each case, as Dr. Schachner remarks, must be decided upon its own merits.

The patient must take his share of the risks attending an operation, the surgeon his share, and the nurse the same.

The patient has the right to expect that every precaution to ensure safety will be taken, and beyond this the responsibility will first fall upon the surgeon and then the nurse or assistant.

Dr. Schachner's view that to a certain extent the surgeon is responsible for things about the operation, and that after that the responsibility must rest elsewhere would seem to be the right stand to take.

A well-defined apportionment of responsibility is, in perhaps the majority of operations, impossible to assign, although, of course, the greater part must necessarily fall upon the surgeon.

THE SURGICAL TREATMENT OF MITRAL STENOSIS.

In expressing an opinion as to the prognosis in cases of valvular disease of the heart, the clinician is often compelled to admit that while he may be able to relieve the symptoms present and restore cardiac compensation he is powerless to exert any curative effect upon the underlying lesion. Although there are now on record a respectable number of cases in which life has been preserved for varying periods of time as a result of prompt surgical treatment of wounds of the heart, the suggestion of a possibility of treating mitral stenosis by surgical methods is nevertheless startling, and this is all the more so as the suggestion emanates from a clinician rather than a surgeon. It is no less distinguished a therapeutist than Sir Lauder Brunton (*Lancet*, February 8, 1902, p. 352) who discusses such a proposition in a preliminary note. Having been struck by the ease with which the constricted mitral orifice could be divided after death he was led to undertake some experiments upon lower animals. As between enlarging the mitral orifice by elongating the mitral opening or cutting through the valves at the middle it was concluded that although the former were the better plan the latter is the more easily performed. Instruments like tenotomy knives were employed, and it was thought better to enter the heart through the ventricle rather than the auricle in order to avoid hemorrhage. The knife should be introduced during diastole to diminish the danger of wounding the opposite wall of the ventricle. The pericardium should be not only opened but also kept open. In the cadaver the heart was exposed by making two incisions from the one edge of the sternum outward to the left, the one along the lower border of the third rib and the other along the lower border of the fifth rib, and connecting their outer extremities by a third incision, and dividing both the soft structures and the fourth and fifth ribs. The window thus made was forcibly reflected upon the sternum, the lung pushed back, the pericardium divided and the knife introduced into the ventricle. If one desired to enter the heart through the auricle, it would probably be necessary to make an incision along the lower border of the second rib, although by pulling on the heart it might be displaced sufficiently to allow the introduction of a knife into the auricle, even if the incision were made at the lower border to the third rib.

There are few clinicians who would recommend such a radical procedure as that here presented, and few surgeons bold enough to carry it out, even if there were patients willing "to balance the risk of a shortened life against the certainty of a prolonged period of existence, which could hardly be called life, as the only conditions under which it could be continued might be worse to them than death."

THE WATER SUPPLY OF LONDON.

That the water supply of the British metropolis has been for long inadequate in quantity, whatever may be its merits with regard to quality, is a too-obvious and palpable fact to all of its disinterested citizens. Rumors have been current, from time to time, for many years, that at length steps were to be taken to relieve the situation, but temporizing has always taken the place of action.

Mr. Long, President of the Local Government Board, has finally introduced into Parliament a "Bill for establishing a water board to manage the supply of water within London and certain adjoining districts, for transferring to the Water Board the undertakings of the metropolitan water companies."

The London water question is said to be a most intricate one—a statement easily to be credited—but into that part of the matter it would be no concern of an American to delve.

The remarks of the *Lancet* on the needs of London, from the water standpoint, will, however, commend themselves to everyone as applying to every large city of the world.

The *London Medical Journal* says: "We must insist once more on the fact that an ideal supply of water for London would ensure that the quality of the water should be pure and derived from sources beyond the suspicion of pollution, and that the quantity should be adequate, not only for domestic supplies, but sufficient to give an unstinted amount for municipal purposes.

The public fountains should not be allowed to run dry, the ornamental waters of London and the canals should be clear and bright, a state of things which could only be made possible by frequent changes of the water, necessarily involving a supply greatly in excess of that which obtains to-day."

It is the undoubted right of every large city to have an abundant and pure supply of water at a moderate charge.

Private individuals or companies should not be allowed to make an enormous profit out of one of the prime necessities of life.

The experiment soon to be undertaken by London will, therefore, be watched with interest by civilized communities throughout the world.

IS DIPHTHERIA DUE TO FOWLS?

Lately the question has been several times anxiously raised as to whether certain infectious diseases can be communicated to the human race by the agency of animals and birds. The declaration has been made that rats can disseminate both scarlet fever and diphtheria to men. Now the suggestion comes from a remote part of Wales that there may be some connection between a disease which is frequently epidemic among fowls and known as roup and diphtheria.

According to the *Sanitary Record*, January 23, Dr. Herbert Jones, Medical Officer of Health to the Rhondda District, when investigating fresh outbreaks of diphtheria in different localities found that in several instances there had been immediately preceding and running concurrently with a diphtheria outbreak a very fatal epidemic among fowls. A bacteriological examination was, in three cases, made of material obtained from the throats of fowls, but without any satisfactory results following, in so far as determining the question of direct infection is concerned. "Some diseases of fowls, such as roup," Dr. Jones proceeds to say, "are so very contagious, and the symptoms so very much resemble those of diphtheria, that there may well be some connection between the epidemic among the fowls and the outbreaks of diphtheria we have so frequently had in our midst during the past few years. In considering whether any practical steps could be taken in the light of the possibility indicated, it appeared to me that it might be advantageous to circulate among poultry keepers a description of the fowl disease, with instructions how to deal with affected birds." The fear of disease being directly communicated from fowls to man, is one so far remote as not to be worthy of serious consideration. However, for the sake of the fowls themselves, and in order to keep up the supply of so succulent and nutritive a food as chicken, it is well that breeders should know how to treat a disease of the nature of roup.

THE VALUE OF AGE AND SEX AS ETIOLOGICAL FACTORS IN THE DIFFERENTIAL DIAGNOSIS OF GASTRIC ULCER AND CARCINOMA.

Dr. William Murrell, Physician to the Westminster Hospital, in the *Medical Press and Circular*, October 23, 1901, published statistics he had collected from his own experience and that of others, bearing upon the above subject. As to the relative frequency of gastric ulcer in men and women, he finds that of 3,114 cases treated by Welch, Fenwick, Lebert, Habershou, Martin, Anderson, and Steiner, 1,003 occurred in men and 2,111 in women, giving a ratio of one man to 2.10 women. When, however, Welch's autopsies are excluded, the ratio is one man to 3.38 women. With regard to the ages at which gastric ulcer occurs, Dr. Murrell finds that a consideration of the figures of four observers gives the preponderance of cases in the decade 20–30, which is in accordance with the view commonly entertained. Respecting the relative frequency of gastric cancer in men and women, Dr. Murrell finds that upon analyzing the figures of six observers, the ratio works out at 6 men to 5 women. Brinton thought that gastric cancer was twice as common in men as in women, but Welch, with his much larger statistics, places the ratio at 5 to 4. The age at which gastric carcinoma occurs, was found from the statistics available to Dr. Murrell, to be between the ages of fifty and sixty.

The conclusions, therefore, at which we arrive are that gastric ulcer is from two to three times as common in women as it is in men, and that it is most frequent between the ages of twenty and thirty. On the other hand, gastric cancer is slightly more common in men, and the majority of cases occur after the age of fifty.

Report of the Health of the British Navy for 1900.

The *Lancet* of February 8 contains a summary of the above report, some of the leading features of which may be interesting to our readers, for the sake of comparison with the navy of this country.

The total force serving afloat in 1900 was 95,830. The total number of cases of disease and injury entered on the sick list was 84,550, which is in the ratio of 882.29 per 1,000—an increase as compared with the previous years, but a decrease of 11.22 per 1,000 as compared with the average ratio of the last three years. The death rate per 1,000 was 7.27, showing an increase of 1.86 per 1,000 as compared with the previous year, and of 2.09 in comparison with the ratio of the last three years. The stations which exhibit the highest death rates are the Cape of Good Hope and West Coast of Africa (20.03), China (17.34) and the East Indies (13.92). The total number of cases of wounds among the British Navy in China was 360, with 69 fatalities. There was a large increase in sickness from dysentery and enteric fever, due to the fighting in South Africa and China.

The figures regarding the health of the American Navy, during a corresponding period, compare favorably with those quoted above. In both navies the cases of dysentery and enteric fever have been largely increased by service under war conditions in tropical climates. Under ordinary conditions, however, there is undoubtedly no healthier life than that led on a man-o'-war.

Deformities of Occupation.

The Literary Digest quotes part of an article on the above subject, contributed by M. Gabriel Prévost to *La Science pour Tous.*

The writer of the article to the French journal declares, and rightly, too, that every occupation leaves some deformity—even the state of being without an occupation. Says M. Prévost, "Complete leisure, if such a thing exists, causes fatty degeneration, and will arrest growth. Diderot was right when he wrote, 'It is the daily occupations that determine, not only the whole size of the figure, but the true proportions of each limb, and of their combinations.' Police magistrates, who have practised eyes, are rarely deceived at first sight about the profession of a workman.

Among professional deformities, some affect the health directly, others only alter the normal attitude of the body, to the prejudice of hygiene and esthetics. The first, which fall within the domain of medicine, still await a proper scientific description. Here and there we read of the necrosis of match manufacturers, the cataract of blacksmiths, miner's paralysis, etc., but there remains to be written a whole treatise of the greatest interest, to indicate the means of guarding against the dangers that beset a numerous class of indispensable workmen devoted to various special interests.

The principle at the bottom of it all is that we were not created to be always standing up nor always sitting down, nor always kneeling, nor always bending over; and that, with the exception of climate, we were created to obey the law of variety, as well in movements as in nourishment. The best proof is that, apart from accidents, longevity attaches to just those professions that give the whole organism the most exercise—those of the soldier, the painter, the sculptor, and the actor.

Among instrumental musicians, flutists and clarinetists may be recognized by the position of their lips, and the puffing out of their cheeks. Harpists and players on the guitar have callosities of the fingers. Pianists have a tendency to exaggerated development of the hands—witness Weber, who could stretch nearly two octaves. Grooms and cavalry officers have bow-legs, and tend to toe in; priests and magistrates and all who wear skirts are inclined to drag their legs, in distinction from soldiers, who raise them."

M. Prévost gives many other examples of the deformities of occupation, and ends by advising one and all, where possible, to be careful of the equilibrium of forces, and points to Sweden, where this precept has been closely adhered to, and where evening gymnasium classes have been established for the two sexes—not those places of torture which turn out acrobats or clowns, but real places of amusement, to which people go as they do to the theater.

A Consideration of Smallpox.

Dr. Nelson Dewey Brayton of Indianapolis, Indiana, has contributed to the *Indiana Medical Journal* a paper with the above title.

The author compares the mild forms observed in Indiana with the severe type of the Atlantic Coast cities, and draws deductions from clinical studies of over one thousand cases, observed at the New York City smallpox hospital.

In the present epidemic in Indiana, the initial symptoms resemble more closely grippe or some kindred malady than smallpox.

The etiology of the disease prevailing in Indiana differs somewhat from that of the Eastern States. This is seen not only in the symptomatology and clinical history of the patient, but in the prognosis of the disease as well. In Indianapolis the cases have been mostly negroes, who give a history of non-vaccination.

In New York the same condition obtained, with this exception, that the cases were notably much more severe. Varioloid was often not only much more generalized and diffused upon the person, but it even showed itself by graver systemic effects than is often exhibited by patients with true variola in this region.

Various theories have been advanced to account for these phenomena, one of the most plausible being that the milder form now so prevalent in the West is an attenuated type of the disease; a tail end of a much severer epidemic, which had already run its course, seen its day, and spent its fury in the far South, notably in Mexico and the West Indies.

New York, on the other hand, had been entirely free from the disease, while for a year and a half it had been widely disseminated through the Western States.

The first cases are supposed to have been brought in by European immigrants. The type of the disease compared with that which had prevailed in the West was much more serious and graver in every way, approaching more nearly in symptoms the classic descriptions of the disease.

Dr. Brayton draws attention to the far greater proportionate number of invasions of the palmar and plantar surfaces in the East than in the West; the greater profoundness of the delirium, the prevalency of the eye symptoms, the frequency of delirium and of albuminuria.

In a few words, while the invasion by smallpox of the Western States has been [illegible] by its [illegible] in the Eastern States the disease has lost its normal course.

The first part of Dr. [illegible]'s paper is devoted to a consideration of the treatment of smallpox, and of prevention against the disease.

The [illegible] at [illegible] both these groups, and the main purpose of Dr. [illegible]'s paper is to [illegible] upon the different types of smallpox in the Western and Eastern States.

As to the cause of this apparently [illegible] of affairs, probably the theory that the epidemic in the West is the tail end of a formerly severe one is as plausible as any advanced.

The result to be drawn from the paper of the Indianapolis physician would seem to be, that there is need of more general and efficient vaccination, and of greater care in diagnosing the mild types of smallpox so widespread in the West.

DISEASES OF THE PHILIPPINES.

Major L. M. Maus, Surgeon U. S. Army, Commissioner of Public Health, Manila, reports on the contagious diseases of the Philippines.

Plague first manifested itself in Manila in December, 1899, and since that date 778 cases have occurred, resulting in 618 deaths, or 79.4 per cent. Every case discovered in the city at present is sent to the Plague Hospital as soon as the diagnosis has been verified by blood examination, and the bodies of those found dead are sent there for cremation unless the friends inter such cases in hermetically-sealed metallic caskets in compliance with the directions of the Board. In order to exclude the possibility of any case escaping the vigilance of the Board, all deaths reported by physicians in the city, where there is suspicion of plague, are examined by one of the medical inspectors of the Board. Great attention is being paid to the destruction of rats, a corps of native rat-catchers having been organized, provided with buckets for holding disinfecting solutions, the collection of dead rats; vessels for rat-bane, etc. Houses or premises where plague occurs, or where dead rats affected with plague have been found, are subjected to a rigid disinfection—such houses being closed for from thirty to sixty days, or until they are considered safe for re-occupancy.

Smallpox has been very infrequent during the past year, only five cases having occurred in Manila during that period. Vaccination is efficient and universal, and the population is considered at the present time to be practically immune.

Pulmonary tuberculosis is very prevalent among a certain class of the citizens—160 deaths having occurred during the two months previous to the writing of the report. This question is regarded as an exceedingly serious one, and in order to secure proper vital statistics in regard to this disease, a blank form has been printed for circulation by the physicians, sanitary inspectors and others of the city. It is believed that the ultimate organization of a consumptive colony outside of the city will become necessary in the near future, as the disease occurs principally among the very poor, and those who live in the crowded districts and under poor sanitary conditions.

Scarlet fever and diphtheria are very rare in Manila, but measles occur occasionally.

The hospitals for the accommodation of lepers are situated in Manila, Cebu, Palestina and Bacolod, and contain about 500 cases. A number of reports have been received from the Governors and Secretaries of the various provinces regarding lepers requesting assistance. With a view to the support of these isolated cases, an appropriation has been submitted to the Commission for necessary funds. Various estimates of from [illegible] to [illegible] have been placed upon the number of lepers living in the Archipelago, but Major Maus judges from information received from various sources that the number is less than [illegible]. In order to secure definite statistics a blank form has been forwarded to the Secretaries of the various provinces and to medical officers and others, for the collection of data, and it is hoped that within a short time the approximate number will be ascertained.

The care of lepers in the hospitals throughout the Archipelago must be regarded as merely tentative, and it is anticipated that during the coming year a permanent colony will be established for them on some suitable island sufficiently distant from the mainland to prevent their return to their homes.

TREATMENT AND PREVENTION OF "SURRA" IN HORSES, MULES AND OTHER ANIMALS.

A circular issued by the Military Governor of the Philippines, dated January 11, 1902, states that an army medical board, ordered to inquire into and investigate a disease of animals known as "surra," has found that liquor potassii arsenitis, injected intravenously, in nearly every case destroys the parasites in the blood, recently shown by Captain A. M. Smith, Assistant Surgeon U. S. A., to produce this disease. Animals so treated are doing well, but the results of such treatment as to permanent cure are not yet conclusive. The circular recommends that this treatment be tried at all points where animals are infected. The board also having found that common house flies taken on sick animals are frequently full of the blood parasites of "surra," the Military Governor therefore orders that hereafter all abrasions or wounds of sick animals are to be kept covered to prevent the possibility of transmitting the disease by means of these insects. As "surra" has become widely prevalent throughout the Philippine Islands, and by its mortality—85 to 100 per cent.—seriously interferes with not only the stock-raising industry and the supply of fresh animal food, but also severely impairs the efficiency of the army transportation service, this latest of the many noteworthy scientific discoveries of the Army Medical Department possesses both a high economic and military importance. Modern medicine is deeply indebted to the recent epoch-making discoveries of army surgeons stationed in the tropics, whose achievements have shown what can be accomplished in a fertile field for investigation by competent observers, backed by a scientific and liberal administration. The medical profession of the country, since the outbreak of the war with Spain, has awakened to a livelier appreciation of the high order of ability and professional zeal which characterizes its representatives in the military service. It is not too much to say that in the last four years a handful of army surgeons, as laboratory investigators and municipal sanitary officials, have done more to advance the science of preventive medicine than all the rest of the medical men of the United States together. It is true that army surgeons, in the nature of things, have unusual opportunity and facility for the pursuit of scientific investigation—that they are making such admirable use of their great opportunities is a cause for the highest praise and encouragement of their efforts by the profession.

News of the Week.

The New York Academy of Medicine.—A stated meeting will be held in Hosack Hall, Thursday evening, March 20, at 8 o'clock. Topic for discussion: Operations for the Relief of Paralytic Deformities, with Special Reference to Tendon Transplantation. (1) Introduction; History; Indications for Operation: by Royal Whitman, M.D.; (2) Deformities, due to Muscular Paralysis; Method of Production; Possibilities in Tendon Transplantation; Combinations that Have Been Made to Correct Deformity: by Wisner R. Townsend, M.D.; (3) Technic of Operation; Results of Tendon Transplantation at the Hospital for Ruptured and Crippled: by Virgil P. Gibney, M.D.; (4) Neurological Questions Involved in Tendon Transplantation, by Joseph Collins, M.D.; (5) General Discussion.

The Late Dr. Henry R. Baldwin of New Brunswick, N. J.—At the meeting of the Society of the Alumni of Bellevue Hospital, March 5, the following preamble and resolutions were passed:

Whereas, In the death of Dr. Henry R. Baldwin our Alumni Society has lost one of its most eminent and respected members, whose noble attributes and high professional character had endeared him to all his friends and to the community in which he lived; be it

Resolved, That we express to his family our deep sorrow and heartfelt sympathy in their sad bereavement; and be it further

Resolved, That a copy of this part of our proceedings be sent to the medical journals for publication.

J. W. S. Gouley, M.D.,
J. F. Erdmann, M.D., } *Committee.*
Irving S. Haynes, M.D.,

The Medical Society of the State of Tennessee will meet in annual session at Memphis on April 8-10, 1902, under the Presidency of Dr. Deering J. Roberts. The meeting will be an important one, as some constitutional amendments involving medical departures from the established policy of the society will then be acted upon. It is requested that members intending to present papers will send the titles of the same to the Secretary, Dr. A. B. Cooke, Nashville.

An Up-to-Date Surgeon.—A British contemporary says of a Parisian surgeon, that he has availed himself of an almost unrivalled opportunity to court publicity by his sensational operation on the Hindoo twins, the details whereof have been obligingly placed at the disposal of the lay Press *urbi et orbi*. To enhance the interest of the occasion the details of the operation were preserved for contemporaneous posterity by the aid of the cinematograph, a device to which this eminent surgeon has shown himself partial on other occasions.

Section on General Medicine of the College of Physicians of Philadelphia.—At a stated meeting, held February 10, Dr. James C. Wilson exhibited "A Case of Osteitis Deformans." Dr. H. A. Hare exhibited "A Remarkable Case of Musical Heart Murmur," in which the symptoms developed suddenly and the adventitious sound could be heard at a short distance from the chest. The condition was thought to depend upon laceration of an aortic leaflet, in consequence of violent physical effort. Dr. Thos. G. Ashton exhibited "A Case of Musical Aortic Diastolic Heart Murmur." Dr. Chas. W. Burr exhibited "A Case of Hysteria in a Small-sized Giant." The patient, a man six feet three inches high, had been apprehended on account of some motor disturbance on the street, the exact nature of which was not understood. When admitted to the hospital he was unable to stand on his feet, and his breathing was excessively rapid—up to 100 in the minute. Under the influence of hypnotic suggestion marked improvement took place. Dr. Howard Fussell exhibited "A Case of Probable Abdominal Aneurism" in a man who, following a fall with injury to the back, presented some spinal rigidity and abdominal tenderness, with a thrill on palpation and a bruit on auscultation. The knee-jerks were exaggerated, the thyroid gland was enlarged, and the man was neurasthenic. Dr. John M. Swan read a paper entitled "A Summary of the Recent Literature on Pneumonia, Bronchitis, Pleurisy and Asthma."

The United States Army General Hospital at San Francisco is nearly filled to the capacity of its 450 beds, and recommendation has been made to the Surgeon-General that such cases as can be moved with safety be transferred to other hospitals, so as to make provision for sick soldiers now returning from the Philippines.

Sickness in the Philippines.—A report from the Philippines covering the month ending January 15, just received, states that the percentage of sick during the month, out of a total strength of 41,116 officers and men, was 6.16. During the month 2,534 cases of sickness were reported. There were fifty-nine deaths, a decrease of eighteen compared with the previous month. The rates for sickness show a steady decrease, in spite of the active operations being carried on in Samar and other islands. Typhoid fever continued at about the same rate, but there was a considerable decrease of malarial disease and affections of the gastro-intestinal tract. Two deaths were ascribed to variola, which disease still continues to attack a few men at isolated stations where the disease exists among the civil population. Among the more important diseases, at the four main hospitals, the sick rates were as follows: Dysentery, 16.7 per cent.; diarrhœa, 6.91 per cent.; typhoid fever, 0.33 per cent.; gastric disorders, 5.07 per cent.; tuberculosis, 1.24 per cent.; venereal disease, 15.54 per cent.; insanity, 2.08 per cent.

Plague in Manila.—Three cases of bubonic plague occurred in Manila during the month prior to January 15, one of the fatal cases being in an American. The Manila Board of Health and army medical officers are making every effort to exterminate rats, and about 500 carcasses are daily brought to the pathological laboratory for examination. Of the total number caught, the percentage of rats affected with plague is rapidly diminishing; up to January 1, the average number found infected amounted to 5 per cent., but during the first two weeks of January less than 1 per cent. were found to be affected with plague.

Filipinos Warned Against American Hospitals.—Near many of the stations held by United States troops in the Philippines hospitals have been established by the military surgeons for the relief of sick and suffering Filipinos, and the benefit of these institutions has done much to favorably impress the natives with the American administration. An insurgent circular, recently issued by insurrecto chiefs, endeavors to counteract this effect by admonishing the Filipinos against the "treacherous Americans." As an example of what the Americans will do the circular says: "In Iloilo the Americans established a public hospital, and then compelled all the very sick people to be taken there for treatment. It was noticed that some of these sick people died very soon. That they might not be bothered with cases that were hard to cure the American doctors administered much poison, and invariably soldiers who had at any time served in the insurgents' army [illegible] In this way the Americans [illegible] to kill off all their enemies. For this reason all who were true to the insurgent cause should, under no circumstances, be taken to an American hospital.

Another insurgent circular calls especial attention to the fact that the Americans now have a chaplain with every regiment. This was necessary, so the circular says, because the number of chaplains previously in the Philippines was quite insufficient to receive the confessions of the Americans killed in battle and dying in the hospitals of disease, and the pope had therefore commanded the President to send more chaplains to the islands.

Honors for Professor Von Bergmann.—The *Lancet* Berlin correspondent announces that Dr. Von Bergmann, ordinary professor of surgery in Berlin University, and director of the University Surgical Clinic, has been invested with the rank of Wirklicher Geheimer Rath (Real Privy Councillor). This dignity, which is the highest of its class in Germany, carries with it the title of Excellency, and is as a rule, conferred only on great officers of State and persons occupying important positions at court, very few medical men having been thus honored.

Appropriations in Germany for Scientific Purposes.—The Prussian Government has set aside 20,000 marks for further study of means of prevention and early diagnosis of typhoid fever, 10,000 marks to the Committee for Cancer Research, and 53,000 marks to be applied to the erection and support of a cancer ward and laboratory in connection with the Charité Hospital at Berlin.

Fatal Vaccination.—The *New York Tribune* reports that on March 6 a Miss Copper of Easton, Pa., died from the effects of vaccination performed by James Dennett, a drug clerk.

London to Have Ambulances.—London will soon have horse ambulances in regular service to respond to accident calls and fires, just as in American cities.

Precautions Against Plague in Melbourne.—A despatch to the *London Times*, March 8, states that special precautions against the spread of plague are being taken at Melbourne. Dirty blocks are being cleaned, rats are being destroyed, and garbage is being burned.

Insurance After Smallpox.—After smallpox the British income-tax underwriters are now offering to insure against an increase in the income tax, and quite a number of policies have been issued.

Mayor Low Scores Dark Tenements.—Mayor Low on Saturday, March 8, expressed his views on the subject of dark tenements. A delegation called upon him, to urge his co-operation in passing the Ash bill now before the Legislature to amend the tenement-house law so that builders may erect tenement houses for six families. The Mayor, in a letter which he sent to the delegation, recorded his conviction that tenement houses with dark interior halls should not be built, and conveyed his desire that Brooklyn apartment houses should be constructed with a view to convenience and health.

$5,000,000 Left to Charities in Glasgow.—James Dick, the Scotch rubber importer and manufacturer, who died in Glasgow on March 7, has willed $5,000,000 to charities of that city.

Method of Killing Animals at Paris Pound.—A lethal chamber for the destruction of lost dogs has been provided for the Paris pound. Thirty condemned dogs are placed in a cage, which is rolled into a platform, which, by hydraulic force, sinks with the cage into the earth and is hermetically closed. Carbonic acid gas is turned on and in the space of forty seconds every dog dies without a struggle.—*Scientific American Supplement.*

Citizens' Union for Public Baths.—Francis C. Huntington, the Chairman of the Executive Committee of the Citizens' Union, has sent a letter to Mayor Low, in which he states that the organization is in favor of the establishment of three more public baths in Manhattan and two in Brooklyn.

Dr. Frank Boas, Professor of Anthropology in Columbia University, and Curator of Anthropology in the American Museum of Natural History, has been elected an honorary member of the Anthropological Institute of Great Britain.

Safety Pin Extracted from Girl's Throat.—Some weeks ago a child in Fall River, while eating, swallowed a safety pin, which lodged in her throat just beneath the vocal chords. The local surgeons were unable to extricate it, but by means of the x-rays the pin was located in the trachea. Attempts were made to remove the pin, but in the efforts it was dislodged, and fell into the branch of the bronchial tube, where it remained three weeks. The x-rays were again applied, and the pin was located in the bronchial tube at the lower end of the third rib. The x-ray photograph was then made use of, and an incision was made in the windpipe at its lowest extremity. After several attempts the pin was extracted.

Cholera in Medina.—Cholera has broken out among the pilgrims at Medina. One hundred and ten deaths from the disease have occurred. Medina, otherwise "The Prophet's City," is one of the principal towns of Arabia, and is 248 miles north by west of Mecca, the seat of the Mohammedan religion. Medina stands 3,000 feet above the sea level. Great numbers of people make the pilgrimage to the Prophet's tomb, it being estimated that one-third of the Mecca pilgrims go on to Medina.

The Georgia Journal of Medicine and Surgery.—Dr. W. F. Fitch, founder, and for many years editor and business manager of *The Georgia Journal of Medicine and Surgery*, published at Savannah, Ga., has sold his interest in the publication to his former associate and co-editor, Dr. St. J. B. Graham, who becomes editor and sole proprietor. The *Journal*, under Dr. Fitch's editorial management, from the appearance of the first issue, merited the support of the profession, and gradually, year after year, made for itself a place among the best medical periodicals of this country. The Doctor will devote his entire attention to the practice of his profession in Savannah, Ga.

College of Physicians of Philadelphia.—At a stated meeting, held March 5, Dr. Richard H. Harte read "A Memoir of the Late Dr. John Asshurst, Jr." Dr. A. O. J. Kelly read a paper entitled "On Multiple Serositis—The Association of Chronic Obliterative Pericarditis with Ascites, with Particular Reference to the Pericarditic Pseudo-Cirrhosis of the Liver of Pick and the 'Iced Liver' (Zuckergussleber) of Curschmann."

Meeting of American Electro-Chemical Society.—The newly organized Electro-Chemical Society, which now numbers 294 members, will hold its first meeting at Philadelphia on April 3, 4 and 5.

Plague Mortality in India is still on the increase. The total for the week ending January 30 was 11,445, against 9,204 for the previous seven days. The epidemic is still very severe in Poona, but the weekly figures have not been published. The disease is spreading in Bengal and Calcutta, in the

Punjab, in Bombay City, in the Madras Presidency, and in the Northwest Provinces. It is anticipated that the next two or three months will show the highest mortality from plague that has occurred since its reappearance in epidemic form in India in 1896.

New Medical Faculty Buildings of the University of Toronto.—The $125,000 building which is being erected for the Medical Faculty and the Arts Department of Physiology will have its interior construction based on the unit system, the system of laboratory construction worked out by Professor Minot of Harvard and his colleagues, for the new medical buildings there.

Smallpox in Glasgow.—Smallpox is raging to a somewhat widespread extent in Glasgow, but the cases, up to the present, have been of a mild type. It is stated that some 10 to 20 per cent. of the inhabitants remain unvaccinated, and the Lord Provost has made an urgent appeal to the citizens to adopt vaccination.

Anti-Mosquito Campaign in West Africa.—Major Ronald, F.R.S., Lecturer in the Liverpool School of Tropical Medicine, sailed on February 22 for Freetown, Sierra Leone, to supervise the work which is being prosecuted against malaria and mosquitos in that region. The expedition, the fifth to be sent out by the Liverpool School of Tropical Medicine, is now under the direction of Dr. Logan Taylor.

Obituary Notes.—Dr. CHRISTIAN FENGER, one of the leading surgeons of Chicago, died on March 7 of pleuropneumonia. He was born in Copenhagen, Denmark, on November 3, 1840. At the outbreak of the Franco-German war he became surgeon in the Red Cross Ambulance Corps, and served through the war. From 1871 to 1874 he was at the Copenhagen City Hospital. He went to Egypt as a member of the Sanitary Council, and was appointed surgeon of Khalifa, district of Cairo. He removed to Chicago in 1877, where he had since lived. In 1878 he became a member of the attending staff of the Cook County Hospital, in 1880 curator of the Rush Medical College Museum, in 1884 professor of clinical surgery at the College of Physicians and Surgeons, in 1893 professor of clinical surgery at Chicago Medical College, and in 1899 he took the chair of clinical surgery in Rush Medical College. During his residence in Chicago he was surgeon at one time or another to the Cook County, Presbyterian, Tabitha, Norwegian, Passavant Memorial, Lutheran, German and German-American hospitals. On his sixtieth birthday, November 3, 1900, a banquet was given to him at which 500 physicians were present. He received many memorials and honors. The decoration of which he was the proudest was conferred upon him by King Christian of Denmark.

Dr. FRANCIS W. LEWIS died at Philadelphia on March 2, at the age of seventy-six years. He was graduated from Jefferson Medical College in 1846, and served as an army surgeon in a military hospital during the Civil War. He was identified with the Children's Hospital since its foundation, and was for many years its president.

Dr. GEORGE W. KING, who, since 1886, had been postmaster at King's Station, Saratoga County, and who was in his seventy-sixth year, died in Saratoga on March 7. He was an ex-president of the Eclectic Medical Society of the State of New York, and the Saratoga District Medical Society. He was one of the organizers of the first society of spiritualists.

Mr. WILLIAM MARTINDALE, one of the foremost British pharmacists, died recently at the age of sixty-one years. He had been president of the Pharmaceutical Society.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

DR. KENDALL FRANKS ON THE SOUTH-AFRICAN CAMPS—CANCER RESEARCH—ERASMUS WILSON LECTURES—DISCUSSIONS ON CANCER—ARSENIC IN HAIRS—SMALLPOX—THE LORDS AND THE CONSCIENTIOUS OBJECTOR.

LONDON, February 21.

THE Blue-book on the concentration camps in South Africa was issued on Monday and is full of medical interest. You will remember that, in consequence of the outcry raised against them, Dr. Kendall Franks was sent by the government to inspect and report upon them. The Blue-book gives an account of his inspection of the various camps, and proves that everything possible was done for the comfort of their occupants. Though certain people at home, and many on the continent, have condemned the camps in unmeasured terms, there are few who would do so in Africa, and Dr. Franks says that before indulging in denunciation they should see the camps themselves. Not only are the "rations ample . . . . but in all the camps there is a liberal supply of medical comforts." On this question it is important that the truth should be told. While reckless falsehoods have flooded the continental press, and produced uneasiness at home among credulous persons, it is shown that the Boer children in the camps have been all along faring far better than the thousands of children of the poorer class in England. The rations for children between five and ten years old include a quart bottle of milk *per diem*, and three pounds of meat per week. From two to five years, two bottles of milk *per diem*, and two pounds of meat per week for soup. Flour, vegetables, and butter are distributed on an equally liberal scale.

The ignorance and credulity of the children's parents have often been blamed as contributing to the mortality, and Dr. Franks mentions some curious notions. A nephew of ex-President Kruger wanted a cow-dung bath for his wife on account of rheumatic pains (a cleaner "cure" for this complaint is the tooth of a horse worn on a string around the neck). The fur of a cat was cut off, roasted, and applied to a child's chest for bronchitis. In another case a goat had been killed, eviscerated and a child put inside, with its head protruding through the opening, made by removing the breast-bone; then the doctor was sent for. The Boers rub the body with cabbage seeds and then sow them for jaundice. As the plants come up, the disease, they believe, fades. For toothache they cut the sufferer's finger and toe nails short, put the clippings into a bottle, with a lock of his hair and water, cork and bury the bottle. Other remedies are quoted, which savor equally of the dark ages, and reliance on which has probably contributed to the mortality, but the extremely dirty habits of the people must have been more to blame.

Dr. Franks found in one tent the "phenomenon" of clean, well-clothed, happy children, and found the cause in the mother, who was Scottish, a great-grandniece of the poet Burns.

The highest mortality was at the Mafeking camp, in October, when large numbers arrived, and there was a dearth of doctors, only two Germans being available for a time, and one of these could not speak Dutch or English, and those two had to look after 800 to 1200 persons for about a fortnight.

Cancer in various aspects has been much under discussion of late. The scheme for research, which I recently wrote about as being projected, has made a short step forward. On the recommendation of a committee, the two Royal colleges have appointed delegates to draw up a detailed scheme for investigating the causes, prevention, and treatment of the disease. The King has communicated an expression of "great interest in the prevention and treatment of cancer, and is glad that the Royal colleges (of physicians and surgeons) are taking up the question of cancer research, and hopes for important results from their action." Unfortunately, the millionaire to provide the funds has not yet put in his appearance.

Among important utterances on the disease, I may cite first that of Dr. Powell White in his Erasmus Wilson Lectures at the College of Surgeons on the 10th, 12th, and 14th of this month. He took for his subject the pathology of tumors, and, of course, had to deal with cancer. In his opinion the difference between simple and malignant tumors is found in the way in which they grow.

The growing area of a cell tumor consists of cells not forming a definite tissue. On the other hand, the tissues in a tissue tumor are of primary formation. The mode of growth, therefore, he thinks, accounts for the penetration of cell tumors into the surrounding structures, instead of [illegible] into the [illegible] and [illegible].

The [illegible] was [illegible] to [illegible] disease [illegible] [illegible], caused by the [illegible] growing [illegible].

Dr. White commented on the [illegible] in which [illegible] typhoid disease and [illegible] inflammation of [illegible] [illegible] and the [illegible].

In his second lecture, Dr. White considered the [illegible] as to the causation of cancer, and laid stress on the distinction between exciting and predisposing causal factors. He has come to the conclusion that the essential [illegible].

This conclusion is fatal to the parasitic theory, which has been prominent during the last eleven years, and he considered at length the views of Plimmer and Gaylord as the authors of the two best papers in support of the theory. He referred to the absence of any agreement among observers as to the nature of the cell inclusions, and as to which are and which are not parasites. Leaving the grounds on which the theory is based inadequate, he then says the theory itself cannot explain the phenomena of the disease. No special extrinsic cause can do so, but they can be explained on the view that the cells take on an independent mode of growth and behave as parasites themselves.

Mr. Plimmer's views thus traversed will be pretty well known to your readers. He restated them at the recent discussion at Liverpool, to which I have once or twice referred. There he showed lantern slides illustrating his "cell inclusions" as well as those organisms which he has isolated from cancer, and the epithelial overgrowth produced by inoculating them.

On the same occasion Mr. H. J. Stiles showed microphotographs in support of his opinion that these cell inclusions originated in degenerations and dropsical changes in the nuclei.

Mr. G. G. Hamilton also showed casts, drawings, and microscopical sections, and controverted some of Mr. Plimmer's views, especially that epithelium is an efficient protective from invasion, instancing the results of feeding animals with tuberculous material in opposition.

Sir Wm. Mitchell Banks, whose paper had given rise to the discussion, also exhibited lantern slides illustrating the development of cancer in breasts affected with chronic mastitis.

Other aspects of cancer have also been under discussion. The subject is always cropping up in some form. The aspect most prolific in suggestions is the treatment, but on this I will only say that with regard to inoperable cases Mr. Henry Morris communicated to the West London Society on the 7th inst. a paper, the tone of which was most pessimistic. His experience at the Middlesex Hospital is unfavorable to oophorectomy. He knew of no permanent benefit from the operation, either alone or supplemented by thyroid treatment. In no case which he had seen had the healing produced by x-rays been sound and permanent, and the cases published as "recovering" or "under process of cure" he considered had been reported prematurely, and would be found to retrogress. The rays produced the same sort of effects, though by a totally different process, as that produced in some cases by Chian turpentine. Mr. Morris gave a test of inoperable cases treated by these methods in the Middlesex Hospital.

Arsenic has been detected in the hair of a certain number of patients with beriberi. Major Ronald Ross says that Dr. Dixon Mann examined for him twenty specimens from Penang and found arsenic in six. It can generally be detected in arsenical poisoning at a certain period. In very recent cases it may not have reached the hair, and in later cases the hair may have been shed or cut. Samples should therefore be taken near the scalp, and the duration of the case inquired into. Dr. Ross thinks it probable that the Penang beriberi is really arsenical, especially as the people there work in factories, and are brought into contact with arsenic.

Smallpox continues its devious way. The variation in the numbers notified from day to day are not of importance, though the newspapers make much ado about every increase or decrease. That is well, however, as it draws the attention of the public to the necessity of prevention in spite of the absurd rumors continually put in circulation by the anti-vacs.

The number of cases now under treatment is 1245. There were seventy notifications yesterday, but on several days the number was half or less that.

In the House of Lords on Monday, Lord Newton moved the second reading of a bill to amend the Vaccination Act of 1898, by repealing the clause which created the conscientious objector. There was quite a lively little debate, the lords evidently feeling that the clause was a foolish one, but the Government [illegible] of its silly [illegible], and actually [illegible] the [illegible] of the bill, which was thrown out by [illegible] to thirty [illegible].

LETTER FROM BEYROUT.

(From Our Own Correspondent.)

[illegible]

Beyrout, January [illegible].

On the 15th of January we are passing from winter into summer. This may seem an anomaly, but from past experience we are sure of it, and those of us who have been born amidst the fogs and snows of our fatherland cry shame upon ourselves, so that we feel chilly at a temperature in which our grandfathers would have been [illegible] the [illegible] of [illegible]. Nevertheless, it comes to pass that we are in the very depth of winter and are shivering somewhat here at a temperature of 58° F. in the shade, and by the chill that is upon us we know that summer is at hand. We have studied the problem from every attitude and we can come to no other conclusion but that the swing of seasons with us is abnormal, not being fourfold as in ancient times, but resolving itself into two—no spring, no autumn, only a hybrid winter (of no climate whatever), and (to make up for it, perhaps) a summer beyond reproach. Reading lately that the sun wears himself out at the rate of half a mile of his diameter a year in giving light, heat and comfort to his dependents, we cannot but think that Beyrout, for at least nine months of the year, must be a favorite of his, as he gives with such an unsparing hand that there is a fear that he may wear himself out before his time. Against the sun we cannot rebel. He is too high above us and too far away, for the matter of that, but we do protest against this Lebanon of ours that, nearly always clad in ermine, leaves us withering here in russet garments from hot and dusty May to sweltering October, and even when our Christmas comes does not shake one snowflake upon us from his hoary locks. Those of us who are the more imaginative do forgive him, however, his monopoly of cool grandeur, in that even in the greater part of our hottest season we are cooled and comforted by the reflection from his icy brow. The underlying villages, too, cannot grumble, as over them he sometimes throws a fold of his snowy mantle.

We are thankful that our principal streets have been reclaimed and made anew, and that when very dusty (which they generally are) they are well watered—so full of dust and so fairly watered that copious, slippery, slimy mud is the result, and that this is never removed, but left to cake and dry and form dust again, we are by no means thankful to the authorities that will have it so. Anyway, there is an elementary assumption of a regeneration that bodes well for the future. The lanes and alleys have lost to a great extent the flavor of the cesspool and seem looking forward to a higher degree of thorough drainage. Premising that their cleansing is not a vicarious one (as there has been little or no rain [illegible] within a month ago), we are justified in expecting at an early date a consummation of cleansing that seemed very far away five years ago, referring more particularly to the holes and corners of our town.

Undoubtedly our past year—taking all its seasons rolled together—with one exception has been a most healthy one, and speaking with the metaphor of the commercial world, the market in spores and germs has been dull. Typhoid has been in its manifestations spasmodic, intermittent and but sporadic at its best, lacking its usual energy and showing symptoms of decadence. Tuberculosis is always with us, thanks to the alternation of dust and mud, but, having no official statistics to go by, we assume that last year it was not so prevalent, for the reason that it was not so popular as heretofore. From a medical point of view its market price has certainly gone down. There were many cases of measles, not rising to the dignity of an epidemic, and unaccompanied, as usual here, by the graver sequelæ of colder latitude. As all, from the highest to the lowest, in the land of the prophet have been educated up to the value of vaccination as a prophylactic, smallpox with us has been reduced to a minimum, and it seems probable that this place will shortly know it no more. Syria does not seem a fitting soil for the cultivation of the weeds of anti-vaccinationists.

The exception we alluded to above was in respect of dengue. In the summer it came upon us as a veritable epidemic storm. In the beginning of summer it commenced a campaign that lasted well into winter. "By many names men call it," and it has as many characteristics as its names are manifold. In the vernacular with us it is designated *Aboo Rikab*, that is to say, "the father of the knee," alluding, no doubt, to one of its earliest and most prominent symptoms. Making itself so generally known and killing nobody, with all its faults we come to look upon it almost as a personal friend. It destroys the popularity of the weather in ordinary greetings. "Good morning, fine day to-day," lapsed into "Good morning, how d'ye do? Have you had Aboo Rikab?"

After serving dengue off the premises, and when we were congratulating ourselves on a good healthy old year and the beginning of a good new one—we had spent just one week of the latter, indeed, in quiet security—on the 7th of January a cry went forth that plague was upon us. Some timid ones forthwith took up their beds and walked, taking shelter among the snows of Lebanon. The veterans of us who had heard the cry before, being doubtful, faced the danger and found it but a scare-crow after all.

It came about this way: "A man" (I translate from the story as told me) "a poor man and a groom came sick from Damascus, walking all the way in the snow and the rain and the cold, coming to Beyrout to seek help for his sickness. When he got to Beyrout he was sick nigh unto death and lay down in a khan (an open space for stabling beasts of burden, with a kind of inn accommodation attached), and, being very tired, fell asleep upon a heap of skins. So the Authority saw him and said, 'This man has been lying on a heap of skins that came from an affected port of Egypt; therefore this man is suffering from plague, and he must be disinfected and sent outside the city to "the Pines" (the inland quarantine quarters), there to be dealt with'; so they sent him, and he died to-day" (the story was related to us on the 9th). And then this unknown and sickly groom, wandering to Beyrout from Damascus (where, by the way, plague was less known than he was, for it was not there and then in existence), became famous, in that his name and circumstances were flashed to Constantinople and back, and all Beyrout was put "under quarantine" for forty-eight hours on his behalf. This segregation was repeatedly imposed upon us like a consequetive sentence until a rumor that the sick man had not travelled from Damascus to Beyrout, but had brought the plague from Bagdad, in company with two others, should be dealt with. As Bagdad was as innocent of plague as Damascus, we hardly see why the city on the Tigris should be amalgamated with the ancient city of Abana and Phaepae in throwing blame upon our Syrian port, and we think it unjust to the man, even with two comrades helping him, who carried a mythical disease from the Persian Gulf to the Mediterranean Sea, that he should die and be buried among us without as much as a bacteriological examination. This was the fact, nevertheless. And so plague entered upon the threshold of our New Year, and so it made its exit.

LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

END OF PLAGUE AND QUARANTINE—WAR AGAINST RATS—INHERITANCE OF DIPLOMAS—OYSTERS AND TYPHOID FEVER—THE BRITISH SEAMAN'S HOSPITAL—OTHER HOSPITALS IN CONSTANTINOPLE—DEATH OF SPIRIDION MAVROYENNI PACHA.

CONSTANTINOPLE, January 31, 1901.

PLAGUE and quarantine are past occurrences. With the end of the year 1901 the former ceased, and the latter was gradually abolished so far as Constantinople was concerned, though it, of course, is still imposed against Egypt, where plague is, apparently, likely to be of frequent recurrence.

From January 17 to September 14, 1901, twenty cases of plague occurred in and around Constantinople, of which six ended fatally. A few more isolated cases were afterwards noted, though, really, all the cases may be considered as isolated occurrences. Thus far nothing has been forthcoming of the treatment adopted except that isolation was practised after proof of plague by bacteriological processes, and that serum was used. "Pestis Minor" the outbreak was considered—"Pestis Politica" the sarcastic named it.

The Health Delegates, after recovery from fatigues of plague and quarantine, directed their attention to the wholesale destruction of rats and mice, as the probable agents of conveying the infection of plague. The CO_2 process of Mons. P. Apery, a pharmaceutical chemist of repute in Constantinople, has been subjected to trials in presence of the European and native members of the Ottoman Sanitary Council. The experiments were successful, as might be expected, in asphyxiating the animals, but scarcely sufficient to demonstrate the utility of the process in disinfecting cargoes. Stronger evidence on this point comes from Marseilles, where the experiments have shown that cargoes may be exposed to the full action of the gas without damage, and at the same time kill the rats and mice, and, possibly, the fleas upon them. This process of Mons. Apery has been under consideration since the year 1899, and has received the approval of various learned sanitarians and bodies, until the Sanitary Department of Marseilles put it into practice, and reported favorably on the results. The International Congress of Hygiene, held at Ostend in 1901, adopted and recommended the process as the best for destroying rats in the holds of vessels without damaging the merchandise. Finally, on December 30, 1901, the Ottoman Sanitary Council, as stated above, subjected the process to trial, since which time they have promulgated most elaborate regulations for disinfecting cargoes and killing rats, but pass over Mons. Apery's process and recommend a proprietary mixture of various gases with sulphurous acid.

The School of Medicine has requested the municipal authorities to take back the diplomas of doctors, pharmacists, vaccinators and midwives who have died, so that other members of their families may not practice under cover of such diplomas, it having been discovered that this is a common practice.

The new Army Medical School at Haidar Pacha, from which so much is anticipated, has apparently come to a standstill. The stately building has not progressed for some months past, probably from want of money.

The Society of Medicine continues its regular meetings, and there have been some interesting cases of abdominal surgery discussed. A scare of typhoid fever from eating oysters brought Prof. Dr. Remlinger of the Bacteriological Institute to the front. On this highly important subject the Professor dilated in the bosom of the Society and in the daily press, and concluded that oysters should be eaten fresh, with lemon juice, in which scientific conclusion all are likely to agree.

A long-delayed project of rebuilding and enlarging the British Seaman's Hospital at Constantinople is again under consideration, and may become a reality. It is to be hoped that another white elephant, like the new hospital at Smyrna, may not result. The hospital craze exists here as much as in America and in Europe. Almost every nationality has its own hospital—Armenian, British, Austrian, French, German, Greek, Italian, Russian—and all attain a fairly high standard of professional skill and trained nursing. The native hospitals are, in most respects, admirable institutions. His Imperial Majesty, the Sultan, has always shown a deep interest in the development of medical science, and the "Hamadiah" hospital at Chichli is a standing monument of his benevolence.

The death of His Excellency Spiridion Mavroyenni Pacha, chief physician to the Sultan, at the ripe age of eighty-three years, has removed a notable member of the medical profession. He was the dean of the medical body in Constantinople, and had a distinguished career. He entered the Turkish service in 1846; became physician to the Imperial Palace in 1859; Professor of Pathology, and chief physician to H. I. M. in 1877. He was a man of varied accomplishments, and was associated for good with nearly all the medical and literary movements in Turkey. The medical schools and Society of Medicine owe much to his skill and energy. He died in harness. The Greek literary "Syllogos," of which he was a founder, went into mourning for fifteen days as a mark of respect.

Up to the present time, February 13, there have been no further cases of plague reported in Constantinople. There is little doing in the medical world. From the doctor's point of view, the last few months have been distressingly healthy.

THE TYPHOID DEATH RATE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: As the typhoid death rate is generally taken as the criterion of purity of the water supply, it is well to inquire if it is worth as much as is usually supposed.

Death from typhoid, we all know, as in every other disease, depends on various things, such as the number sick, the intensity of the disease, the resistance of the patient, etc. Since other factors than the number sick enter into the death rate, it is evident that there can be no constant relation between the death rate and the purity of a water supply; if 10 per cent., or any other ratio, always died, such would be the case, but such is not the fact, for the differences between the number sick and the number who die are very great.

Take, for example, a case in which the death rate is only 1.4 per 10,000; all sanitarians would judge this to be a city supplied with fair drinking water. Now, compare this with another city where the death rate is 7.0 per 10,000; this city would be considered to be in poor sanitary condition, yet it is better than the first, for in the latter there were only 15 per 10,000 sick of typhoid,

[illegible]

[illegible]

[illegible]

[illegible]

[illegible] Why, then, not use the sick rate?

The rates here [illegible] were taken [illegible] the annual statistics of a number of [illegible] and illustrate the great differences which are likely to occur between the death rate and the sick rate.

Harvey B. Ba[illegible], M.D.

Remote Results of the Bloodless Method of Reduction in Congenital Luxation of the Hip Joint.—M. Redard gives the results in fifty cases, in the greater number of which operation was performed from two to four years ago. No grave sequelæ were noted in any case. Functional results were excellent in eight cases of unilateral luxation, the patients walking with ease and without the slightest limp. In thirty cases, walking was very satisfactory, only the slightest limp being perceptible. In two cases prolonged exercise brought great fatigue. In two cases of bilateral luxation walking was normal, while in three there was a little stiffness and slightly swaying gait. The author concludes that this method of reduction in the majority of cases produces absolutely satisfactory results, and should always be given the preference in children under seven years of age.—*[illegible] di Ortopedia.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, March 6, 1902.

Report of Two Cases Operated on for Deformity of the Nose.—[illegible]

Contribution to the Study of Spinal Fracture, with Special Reference to the Question of Operative Interference.—[illegible] W[illegible] concludes that there are no symptoms which establish otherwise than through their persistence [illegible] crush of the cord. Total flaccid paralysis, anæsthesia of [illegible], total loss of reflexes, [illegible] and [illegible] point to complete and irreparable transverse lesion, but the onset of such symptoms does not preclude a certain degree at least of restoration of function. Operation, [illegible] is the only measure, and should take place not sooner than a few hours after, nor later than a few days after, the injury. We have no infallible guide to the extent of the lesion. The operation at the worst does not materially endanger life nor affect unfavorably the course of the case, and may at least reveal the lesion and lessen the pain; it may sometimes save a patient from death or from helplessness of the most distressing character. Instead of selecting the occasional case for operation we should rather select the occasional case in which it is contraindicated (great displacement of vertebræ, of a high and rising temperature, profound shock, or a moribund condition). The dura should be opened freely, it need not be sutured, and drainage is not necessary.

Journal of the American Medical Association, March 8, 1902.

Symphysiotomy.—E. A. Ayres reports thirteen cases without a death from the operation. Possible objections he enumerates as wounds from the vulva, opening of a joint, hemorrhage, perisymphysial lacerations during delivery, injuries to the sacro-iliac joints, and failure of joint union and subsequent crippling. He states that the following are the requirements necessary to secure the safest and best results: (1) Constant apposition of the pubic bones with even coaptation, but without compression. (2) Ability of the patient to empty the bowels and bladder without disturbance of the pubic joint, and ease of cleansing the genital and anal regions. (3) Freedom of restraint of the body above the pelvis, and of the limbs, whereby lactation can be performed and the great discomfort of prolonged restraint avoided. (4) The avoidance of bedsores. He would consider symphysiotomy justifiable in certain malpresentations (impacted occipitoposterior and chin presentations) and also where there is obstructed delivery due to pelvic incapacity. The operation should give place to premature delivery when the forecast of impossible delivery without major operation is sure and the patient prefers it, or the physician is not accustomed to major operative work. It should give place to Cæsarean section in cases in which there are obstructions to vaginal delivery by tumors, exostoses, cancer and pelvic contractions greater than the rule given above allows for symphysiotomy.

The Indications for Myomectomy in Young Married Women, with a Report of Four Cases of Strangulation of Fibroids During Puerperal Involution.—Edward Reynolds enumerates the diagnostic points of this condition as follows: (1) The appearance in the early part of the puerperium of severe intermittent paroxysmal pains, bearing close resemblance to labor pains, and referred to a definite spot at which there is acute tenderness. (2) The appearance after a few hours of these pains of the symptoms of a pelvic peritonitis, and often in an alarming degree. (3) The detection on physical examination of an irregularity in the uterine wall at the tender spot, not necessarily of large size and possibly to be made out only under anæsthesia. The principles of treatment should be: (1) The control of the pain by morphia, and if this is not promptly successful, by brief but profound anæsthesia, which should be succeeded by relief, and should be repeated whenever the pain reappears. (2) If the preceding measures fail, and the patient is still in good operable condition, an immediate myomectomy is probably the best treatment. (3) If the condition has remained undiagnosticated until the peritoneal symptoms are extreme and an abdominal operation will probably involve a high mortality risk, and if in this case the tumor is in any way accessible from below, its free puncture and the drainage of the contained serum may probably be relied upon to terminate the attack, and permit a safe removal of the tumor at a later date, should that be necessary.

The Rôle of Certain Non-Granular and Granular Somatic Cells in Infection.—Under this heading H. F. Harris includes plasma cells, endothelial cells, eosinophile cells, and mast cells. The first variety are to be regarded as always indicating the beginning formation of cicatricial tissue. It is probable that they are the real fibro-blasts, the collagenous tissue being formed by a process of secretion around their periphery. After a certain amount of fibrous tissue has been formed around them, they seem to be what are commonly, but erroneously, called fibroblasts. As cicatricial tissue develops, these cells undergo retrogressive changes, break up, and the resulting débris is carried away by means of the lymphatics or by the phagocytes. This, however, does not always seem to be the fate of these cells, since a certain number of them become branched, their protoplasm loses its basophilic affinities, and the cells remain in the parts as fixed connective-tissue cells. Concerning the second variety, the author expresses complete ignorance. The third variety are generally regarded as being old polymorphonuclear leucocytes. No significance attaches to their presence in infections. Of the last variety there are four kinds—the mast cells of Ehrlich, of the lymphatics, of the blood and the muscular-fiber mast cell. Inasmuch as these cells have a tendency to disappear in acute inflammatory conditions, their absence under these circumstances is of more or less significance, but in chronic processes they not infrequently considerably increase in number, and their presence under these circumstances may be suggestive of the character of the condition. This peculiarity seems to be of especial importance in differentiating so-called inflammatory conditions from sarcoma.

New York Medical Journal, March 8, 1902.

The Sideroscope.—This article by T. R. Pooley is written especially to show that the author was the first to employ the magnetic needle for the purpose of determining the presence of iron or steel in the eye. He details his initial experiments and the various stages of elaboration of the instrument now used for the purpose and called the Sideroscope.

The Severing of the Vasa Deferentia and Its Relation to the Neuropsychopathic Constitution.—Commenting on the fact that castration has been objected to, although it, of course, accomplishes the desired object of rendering imbeciles sterile, H. C. Sharp advocates the severing of the vasa deferentia as accomplishing the same result without the depressing subjective effect coming from the knowledge of a loss of sexual power. He states that after having personally severed the vasa deferentia in forty-two patients, whose ages ranged from seventeen to twenty-five, he is prepared to speak most favorably of the operation, and to state positively that it does not impair the sexual power of those operated upon, that they improve mentally and physically, in that they increase in flesh, feel that they are stronger, sleep better, their memory improves, the will becomes stronger, and, that while prior to the operation they made no advance in school, their advance is now fairly satisfactory. He advocates the method of operation in which the vasa are severed in the scrotal region.

Nævus Verrucosus Associated with Certain Anomalies of Pigment.—H. Taylor reports the case of a boy of nineteen years without any history of tubercle or syphilis. Only the right side of the body was affected, and the condition was apparently congenital. Over the right pectoral region there was a dense crop of pigmented, nonhairy warts, extending into the axilla, and—though somewhat thinning out—half way down the inner aspect of the right arm. At about the level of the nipples the warts reached the median line of the body, then, gradually disappearing, were replaced by a line of reddish-brown pigment continued down to the umbilicus, where again a few growths appeared.

From the umbilicus to the pubes another faint brown line could be traced, unaccompanied by any warts, but on the right side of the scrotum and penis some could be found, and with them a few reddish scars, the site of previous ones which, the patient stated, had "dropped off." Similar scars could be seen on the right side of the forehead, nose, and chin, the result of treatment by the actual cautery. Down the inner side of the right leg, from the groin to the inner malleolus, was another faint line of pigment which, becoming more marked behind the ankle, was apparently merged into five or six oval-shaped, raised, colorless patches of a leathery consistence, placed along the inner edge of the right foot.

The author considers, as the noteworthy points of the case, the marked manner in which the lesions were rigorously limited to the right side of the patient, their distribution in the track of certain cutaneous nerves, the alteration of deeply-pigmented papillomata, with merely the presence of pigment in the skin, and finally the merging of this pigmented condition into decolorized patches.

American Medicine, March 8, 1902.

Proteosuria.—H. O. Mosenthal and William J. Gies believe, from their experiments with Freund's method for the detection of proteose, that it is not a differential process, and that it cannot be safely applied to the urine or feces as a peptone test. They prove that peptones, proteoses, and gelatins in urine and feces may each give positive results with it. They indicate, also, that seromucoid in the urine might affect the final reaction. Improved methods of detecting proteose and peptone in urine in the presence of each other are described.

Tuberculous Pericarditis, with Effusion; Repeated Tappings; Bacilli in the Exudate; Recovery.—Florence R. Sabin reports the case of a boy, aged twenty, who was admitted to the hospital complaining of pain over the heart. Gradually the signs of pericardial effusion developed. Still later, the effusion had increased till it was considerable in amount, as indicated by the following signs: The apex impulse was no longer visible; there was distinct bulging of the precordium; there were signs of compression of the left lung; namely, flat tympany in the left axilla, though not at the back. During the history of the case frequent tappings were made, and proved of great value. Tubercle bacilli were found in the pericardial exudate; and at the fifth tapping a differential count of the leucocytes of the exudate was made, and of 1,000 counted, 98.5 per cent. were small and 1.3 per cent. were large mononuclear forms, while only 2 per cent. were polynuclear forms. This ratio was constant.

Concerning the Hypnotic Action of Apomorphin Hydrochlorate in Alcoholism.—Warren Coleman and John Metcalfe Polk conclude that: (1) To obtain a hypnotic action with apomorphin it should be given hypodermically; (2) The dose cannot be fixed. It is well to begin with a small dose—1-30 gr. or less—and to repeat this, or give a slightly larger dose, within a short time. Further doses should not be given after vomiting occurs, until several hours have passed; (3) Doses repeated in two or three hours have but little beneficial effect; (4) The administration of apomorphin should not be repeated in patients who are weak; (5) The duration of the hypnotic action is only a few hours, and when the patient awakes his condition is practically unchanged, except in "ordinary drunks;" (6) The best results are obtained from apomorphin when it is followed in two or three hours by some recognized hypnotic, as bromid, chloral, paraldehyd, etc.; (7) Solutions of apomorphin are unstable and should be freshly made. Old solutions should never be used; (8) Apomorphin may be employed as a hypnotic in selected cases of alcoholism. The best results in the experience of the writers were obtained in "ordinary drunks" and in cases verging on delirium tremens. But in some of these cases the drug had no effect whatever; (9) The administration of apomorphin to patients in delirium tremens is without beneficial result, and may even be attended with danger from its depressing action. The writers have given, in the main, the results obtained with apomorphin in 300 patients presenting alcoholism, who have been under their care.

Medical News, March 8, 1902.

One Way to Fight Contagion.—Charles V. Chapin gives most valuable suggestions about teaching cleanliness to children. Teach them not to spit. To spit on a slate, floor, or sidewalk, is an abomination. Not to put the fingers in the mouth. Not to pick the nose. Not to wet the fingers with saliva in turning the leaves of books. Not to put pencils into the mouth or moisten them with the lips. Not to put money into the mouth. Not to put pins into the mouth. Not to put anything into the mouth except food and drink. Not to swap apple cores, candy, whistles or anything that is habitually put into the mouth. Teach them to wash the hands and face often. Teach them to turn the face aside when coughing and sneezing. Children should be taught that their bodies are their own private possessions and that personal cleanliness is a duty.

Somnolence and Loss of Memory Resulting from Cholesteatoma of the Middle Ear.—Francis R. Packard reports this case. His patient was a man twenty-three years old, who for upwards of twelve years had had a discharge of foul-smelling pus from the left ear. For the last year he had noticed that his memory was failing,

[illegible]

Urticaria of the Upper Respiratory Tract.—[illegible] There was great [illegible] and burning and itching of the whole body. The tongue was much swollen. The voice was almost aphonic. The uvula was lobulated, due to two large wheals, and the mucous membrane of the mouth, larynx, [illegible] and the aryepiglottic folds as far as could be seen, were swollen. The [illegible]pharynx was sprayed with a solution of cocaine and, as the swelling [illegible], the larynx was then seen to be extensively involved, but there was apparently no eruption below the false cords. The patient was given small pieces of ice in the mouth, a dilute carbolic wash was used on the dermal surface, and the bowels were freely moved by high [illegible], followed later by a large dose of salts. The [illegible] and ice rapidly reduced the swelling of the respiratory tract, and within an hour the mucous membrane had resumed its normal appearance. There was nasal [illegible] from the presence of wheals, but this also subsided. During the height of the attack there was apparently complete deafness due to the occlusion of the tympanic cavity and Eustachian tubes by wheals. The [illegible] cause as regards the liability to attack of the respiratory tract is apparently unknown. No difficulty should be experienced in recognizing urticaria of the upper respiratory tract when the lesions are also present upon the cutaneous surface, and it is only in cases where they are limited to the mucosa that the diagnosis will present any difficulty.

[illegible], March 8, 1902.

The Identification of the Colon Bacillus by Reactions Produced in Culture Media Containing Neutral Red—Observations on Reactions of Other Bacteria on the Same Media.—Randle C. Rosenberger concludes (1) That while not affording a specific reaction in the case of the bacillus coli communis, neutral red agar should be classed as a valuable differentiating medium. (2) The typhoid bacillus, while it does not cause a fading of the color of the medium, never gives rise to the fluorescence noticed in some cultures of the bacillus coli communis. (3) Further, the test medium should not be depended upon as the only differentiating one in the examination of water, as several very common bacteria found in the water give the same reaction.

An Outbreak of Chickenpox Among Children Convalescent from Smallpox, with Remarks upon the Relationship of These Two Diseases.—J. F. Schamberg reports this epidemic. A child suffering from chickenpox was sent to the smallpox hospital as the result of incorrect diagnosis. The child was vaccinated and did not contract smallpox, but chickenpox remained in the children's ward for three months. The attacks were in most cases mild. The chickenpox efflorescence appeared in the majority of the patients from the twentieth to the thirty-fifth days of their smallpox eruption. Most of these children did not enter the hospital till the third or fourth day of the smallpox eruption; so it will be seen that many of them did not contract chickenpox until about a month after their exposure. Most of these patients received the chickenpox infection during the desiccation stage of smallpox, or at about the end of two weeks of the eruption of smallpox. Although certain acute exanthemata may exist simultaneously in the same subject, it is far more common for the second infection to develop during the convalescence from the first. Varicella and variola are as a rule easily [illegible] each other. They are, however, [illegible] different diseases.

[illegible]

Certain Diseases of the Blood-vessels.—[illegible] (2) The [illegible] (3) The early age at which varix usually develops. (4) The fact that [illegible] (5) The [illegible] condition in the majority of [illegible] and (6) the [illegible] of a varicose vein. [illegible] for operation.

Hypostatic Albuminuria of Splenic Origin.—H. D. Rolleston calls attention to the fact that in some patients with considerable splenic enlargement rest in bed or in the recumbent position may be accompanied by albuminuria, and that the albumin may disappear from the urine when the patient assumes the erect position. While the albuminuria is probably due to the mechanical pressure of the spleen on the left renal vein in the recumbent posture, the occurrence of this intermittent or hypostatic albuminuria is very far from being constant in cases of splenic enlargement. In this it resembles albuminuria from chronic venous engorgement induced in other ways, as, for example, in the backward pressure of mitral disease. It does not depend on the size of the spleen, for hypostatic albuminuria may be, and, indeed, usually is, absent when the spleen is very large, and may be present where the spleen is relatively smaller. It is possible that its occurrence or absence may depend on some difference, such as elongation, in the condition of the suspensory peritoneal ligaments of the spleen, which thus determine or prevent direct pressure on the left renal vein. On this point there is as yet no anatomical evidence. It is also conceivable that the appearance of albuminuria is dependent on an underlying want of vitality or nutrition in the kidney, which, though not sufficiently marked to induce albuminuria under ordinary conditions, does so when chronic venous engorgement is superadded. This is to some extent supported by the observation that in one case albuminuria disappeared from the night urine after the patient had been some time in hospital and had somewhat improved under treatment; subsequently after a slight attack of influenza the night urine again contained albumin.

The Anatomy, Physiology, and Pathology of the Imperfectly-Descended Testis.—In the Hunterian Lectures this subject is considered by W. M. Eccles, who enumerates the causes of the condition as follows: (1) Conditions associated with the mesorchium: (a) The mesorchium may be too long, the testis would therefore probably hang too freely in the abdominal cavity, and would thus be prevented from engaging the [illegible] of the processus vaginalis; (b) adhesions between the peritoneum forming the mesorchium and the adjacent portion of the serous membrane, generally the outcome of intrauterine fetal peritonitis; and abnormal persistence of the plica vascularis. (2) Conditions associated with the testis and its component parts: (a) the spermatic vessels may be too short, (b) the vas deferens may be of insufficient length, (c) the epididymis may be abnormal in size, (d) there may be a fusion of the two testes—synorchism; and (e) certain forms of hermaphroditism. (3) Conditions associated with the gubernaculum testis: (a) absence of the upper normal attachments of the gubernaculum, (b) deficiency of its muscular fibers, and (c) deficiency or absence of its scrotal attachments. (4) Conditions associated with the cremaster: (a) retraction of the testis after it has descended to its usual habitat in the scrotum, and (b) want of action of the internal fibers of the cremaster before the testis has reached the inguinal canal. (5) Conditions associated with the route along which the testis has to pass: (a) ill-development of the inguinal canal, (b) ill-development of the superficial abdominal ring; and (c) ill-development of one-half of the scrotum; (6) Other conditions, such as the wearing of a truss preventing the onward passage of the organ into the scrotum. In some cases the body of the testis may be retained in the canal, while the epididymis and vas pass into the scrotum.

Physiologically, we may have one of the following conditions: (1) Arrest of one testis, with complete descent and development of the opposite gland, only very rarely associated with any deficiency in bodily growth; (2) Arrest of both testes, when they are ill-developed, usually accompanied by some more or less pronounced want of development of the body as a whole; (3) Arrest of both testes, but good development of both glands, but rarely followed by, or connected with, imperfect growth of the body; (4) Arrest of both testes with want of development of only one gland not necessarily accompanied by a diminution of bodily growth.

British Medical Journal, March 1, 1902.

Remarks on Congenital Cysts of the Tongue.—John Ward Cousins states that congenital cysts of the tongue are not a common class of tumors. They generally occur in the middle line between the genio-hyo-glossus muscles, or between the genio-hyo-glossus and the mylo-hyoid. Sometimes they remain unchanged for many years. Their contents consist of soft sebaceous matter, and occasionally they contain also hair and solid masses of true dental tissue. The cyst wall is lined with squamous epithelium, and is of delicate structure and easily torn, but it is occasionally thick and fibrous. These tumors do not fluctuate, but feel elastic and tense on palpation. They are generally observed in young adults, and their existence is often overlooked during infancy and early life. They are painless and increase with the development of the individual. Irritation is apt to develop inflammatory changes in them. Congenital cysts have their origin in the accidental displacement of some epithelial structure.

Treatment of a Case of Scirrhus Recurrent in Five Years in a Patient Aged Ninety-three; Improvement.—E. A. Peters reports this case. The original growth was said to have been removed with the left breast thirteen years before. The recurrence had been noticed by the patient eight years later. At the commencement of the Röntgen treatment, the growth measured three by two and three-quarter inches. It had a well-raised margin, covered by thin red epidermis, while the center was occupied by an irregular ulcer. Large tender glands could be felt at the edge of the lesser pectoral muscle. Some of the surrounding veins were distended, and there was pain of the extensor surface of the forearm and middle digit. A ten-inch coil was employed, to give a parallel discharge, four to seven inches in length, with Watson's veil break worked at maximum speed. A "penetrator" tube of medium hardness was used throughout; it gave primrose-green iridescence with no intrapolar flow of violet light. The tube glowed even when discharges were passing across an interval of only two inches on the coil. The exposures were made two or three times a week for ten to twenty minutes; the distance of the tube from the skin varied from two to four inches. The improvement was rapid and marked; the discharge and pain had decreased to a minimum. But, unfortunately, the patient developed croupous pneumonia and died. Only ten applications had been made.

A Clinical Lecture on Feeding in Gastric Ulcer.—Lauder Brunton declares that a gastric ulcer must not be irritated by anything that will do harm to it, either mechanically or chemically. Amongst the things that injure mechanically are hard, indigestible things that really play the part of sandpaper. For example, seeds may be considered absolutely indigestible. Fish bones may sometimes give rise to great pain and danger. Cellulose, which is found in various vegetables, such as cabbage, and in the form of fruit skins, is quite indigestible in the stomach. Strings are found in meat, and it is upon the less or greater size of the strings of meat that their digestibility or indigestibility depends. Anything hard, that is likely to plug the pylorus, tends to increase the acidity of the stomach, which in cases of gastric ulcer is generally over the normal, while it should rather be diminished. Chicken, then, is better than mutton, and mutton better than beef in this respect. Milk sometimes comes under the head of stringy food. Lime water helps to prevent the stringing of milk, as does also the process of peptonizing it. Mastication will do much for these patients. In cases of gastric ulcer begin by giving the patient rest in bed, with feeding by the rectum a few days, then careful feeding by the mouth while rectal feeding is continued. The first food given is generally a small quantity of milk, and a tablespoonful of milk with the same quantity of lime water every two hours. The quantity of the milk may be gradually increased, while that of the lime water is diminished for a few days. Then custard may be tried, and pounded fish, followed by pounded chicken. Chocolate may also be given. When dealing with starchy foods, they must be made into a paste with cold water first, while hot water is added afterward. Stale bread is far more digestible than fresh bread.

Deutsche medicinische Wochenschrift, February 13, 1902.

Death from Paralysis of the Heart, Resulting from Chloroform Narcosis.—L. Laqueur reports a death, at the beginning of chloroform anæsthesia, due, it seems certain, to the paralyzing effect of the drug upon the heart. The chloroform used was of faultless purity and was carefully administered, drop by drop, through an Esmarch inhaler, a sufficient amount of air being admitted. At autopsy there was found the following series of pathological changes: Enlargement of the thymus gland, deep and superficial glands and spleen. No other significant alterations were found, although the bronchial glands showed a small caseous deposit. The author reviews the literature of this subject, and finds that many sudden deaths during chloroform narcosis have occurred in patients who on autopsy showed a similar series of pathological changes. Especially is this true with respect to the enlargement of the thymus, deep and superficial cervical glands and tonsils, and he regards such patients as especially bad subjects for the administration of chloroform. It is generally difficult to accurately diagnosticate enlargement of the thymus during life, although occasionally this can be done, as has been demonstrated by Daut and Biedert. In view of this fact, great hesitation should be observed in advising the use of chloroform anæthesia in persons who show hypertrophy of the deep and superficial cervical glands and tonsils, whether or no such persons possess an enlarged spleen. A careful and detailed examination of these structures should be made in every case in which chloroform administration is proposed.

Infection and Auto-infection.—A. Wassermann advances some new ideas with respect to the nature of infection and auto-infection. In order that infection exist it is necessary for pathogenic microorganisms to gain admittance into the body and multiply therein. The human body, under certain conditions, is provided with means of protection against this infection, and there are present in the blood serum substances which are able to kill infecting bacteria in large number. Such death is brought about by the combined action of two substances, the so-called immune body and complement. The first of these substances is stable and not easily destroyed, while the second is unstable and very easily destroyed. Since the action of the complement is to bind the immune body to the infecting microorganism and thus cause its death, it is evident that a given bacterial immunity is largely due to the amount of complement present in the given serum. Investigation has shown that the blood in certain portions of the body contains more of the complement than it does in other portions. This may occur normally or under pathological conditions. Furthermore, a reduction in toto of the quantity of complement present in the body may be produced by the removal of the liver, chronic lesions of various internal organs and suppuration. Recent observations have shown that in many infectious diseases the site of production of these protective substances is the bone marrow, and also that in numerous instances the infecting bacteria must gain admittance into the bone marrow before the protective reaction is set up. Oftentimes these organisms remain alive in the bone marrow long after the disease has disappeared, but are kept from multiplying by the power of the protective substances there present. If now any cause, such as traumatism, becomes operative in reducing the amount of protective substances in such a location, the bacteria remaining there become active, and local disturbances, such as periostitis, arise. In this manner is to be explained the etiology of many hitherto unexplainable bone lesions.

Berliner klinische Wochenschrift, February 17, 1902.

Plastic Nasal Surgery.—Fritz König communicates a new plastic surgical method for use in correcting defects of the alæ nasi, brought about principally through the loss of tissue as a sequel of lupus. The common practice has been to transplant cutaneous tissue from the neighboring regions, as the cheek or upper lip. This, unfortunately, is only the correction of one deformity by the production of another, as an unsightly scar is left at the place whence the transplanted tissue has been removed. Furthermore, in these defects of the alæ nasi, the cartilage is involved in the loss of tissue, and such cannot be satisfactorily replaced by a simple cutaneous structure. In order to obviate these disadvantages König proposes to use a portion of the concha auris for transplantation purposes. This portion he takes in its entirety from the superior and posterior region of the external ear which, if desired, can be subsequently covered by the hair, and the [illegible] A case in illustration of the above-described operation is submitted by the author.

Fracture of the Humerus by Muscular Contraction.—Millerd reports an interesting case of this rare accident. [illegible] He [illegible] the elbow fixed [illegible] upon a table, the hand [illegible] the opponent [illegible] the arm [illegible] and the corresponding [illegible] At the second trial something gave way in the patient's arm and acute pain therein immediately followed. Examination showed that the humerus had been fractured about a hand's breadth above the elbow joint. After thoroughly examining into the conditions present Millerd concludes that this accident was due to a powerful muscular contraction of the brachialis anticus. A picture is added which demonstrates the nature of the contest indulged in.

Plastic Tendon Surgery.—Richard reviews the technic of plastic tendon surgery, and is very enthusiastic over the results thereby obtained. Such operations are of special utility in correcting the deformities and restoring the functions of paralyzed limbs resulting from hemiplegia, Little's disease, and the spinal and cerebral paralyses of children. Good results are also obtained in congenital clubfoot and recurrent flexion contractures of the knee joint. He reports a case of deformity and partial loss of function of the hand and fingers which particularly affected the thumb and index finger, and rendered all accurate manipulation of the hand and fingers impossible. In this case by uniting the extensor longus tendon of the thumb with the flexor longus tendon of the index finger a partial restoration of function was obtained. An interesting fact with regard to these tendon operations, so far as recovery of function is concerned, is that the desired result is very often not obtained until a considerable period of time after the operation has elapsed.

Münchener medizinische Wochenschrift, February 18, 1902.

Treatment of Phimosis.—F. Wenzel says that many cases of phimosis may be successfully treated without the employment of operative procedures. Especially is this the case in the newborn and in boys under four years of age. In such instances he at first dilates the contracted orifice of the foreskin with a small sound, and then introduces a suitable forceps, and, by forcibly separating its blades, carries dilatation still further. This should be repeated in several directions, and the adhesions between the foreskin and the glans broken down. By such methods one is able to dilate the contracted orifice sufficiently to strip the glans. This is then carefully washed with an antiseptic solution and covered with an antiseptic powder, which should be repeated after every urination. By repeating these dilatations two to four times, at intervals of from eight to ten days, a permanent satisfactory result is obtained. When operation is necessary the so-called oval incision of Witzel is to be strongly recommended as preferable to either circumcision or dorsal incision. By this method the dorsal surface of the glans-penis and urethral orifice are freed and a much more sightly result obtained than by the old methods. The operation may be performed under cocain anæsthesia in adults. In patients from one to fourteen years of age general anæsthesia is preferable. In infants no anæsthesia is required.

Acute Spinal Osteomyelitis.—Alfred Schönwerth thinks that this disease is not as uncommon as would appear from a review of the literature which records only forty-one cases. As evidence of this opinion he reports the following case, in which a correct diagnosis was only reached post mortem. The patient was a healthy man, twenty-seven years of age, who gave a good personal and family history. He was suddenly seized with spinal pains of moderate severity, unaccompanied by chills or fever. These pains rapidly increased in severity, and within twenty-four hours bodily movements, especially bending of the spine, became very painful. Constitutional symptoms appeared and the temperature rose to 39.4° C. Examination showed the presence of a small furuncle on the dorsal surface of the right hand, which, however, caused the patient no inconvenience. The spinous processes of the twelfth dorsal and first lumbar vertebræ was [illegible] tender upon pressure. [illegible] backwards was elicited by pressure upon the anterior extremity of the left lower rib. Posteriorly to the left of the lumbar region there was a circumscribed tender region. All the symptoms [illegible] a probable diagnosis of abscess of the [illegible] was made, and an operation undertaken therefore. Upon incision, however, it was found that no abscess was present as supposed. The wound was packed with gauze and [illegible] possible. Following this the fever and general condition markedly improved for a time, and the tenderness [illegible] in the region above noted decreased. Indeed no pain was thereafter produced by pressure upon the anterior extremity of the left lower rib. This improvement was, however, only temporary, and the patient rapidly became worse and died with the characteristic symptoms of general sepsis, which was the clinical diagnosis made at death. On autopsy evidences of osteomyelitis were found in the first lumbar vertebra at the junction of the left spinous process and body. None of the other vertebræ were affected. From the purulent exudation at this point pure cultures of the staphylococcus pyogenes aureus were obtained. This microorganism was also cultivated from the blood. The author believes that the origin of the osteomyelitis is to be traced to the furuncle which was present on the hand.

Hypophrenic Pain and Neurosis of the Cœliac Plexus.—F. A. Hoffmann designates as hypophrenic those pains which have their origin beneath the diaphragm and which may or may not radiate in various directions. Such pains are to be divided into two classes—those which occur only as the result of external pressure and those which occur spontaneously and without assignable cause. In our present knowledge the first class is not of any considerable importance from a diagnostic standpoint, since we cannot by eliciting these pains in various locations definitely determine which of the abdominal organs is affected. A careful consideration of the spontaneous pains is, however, of great value as regards accurate diagnosis. Especially does this apply to the direction in which such pains are radiated. In liver, stomach, spleen and pancreatic diseases the pain takes an upward direction, while in pathological conditions of the abdominal aorta, suprarenal capsules and solar ganglion it is radiated downwards. Occasionally in the first-named diseases there may be posterior pains which are radiated downwards towards the sacral region, but as a rule even the posterior pains are directed upwards towards the shoulder—in liver disease towards the right shoulder, in spleen and pancreatic disease towards the left shoulder and in stomach disease straight up the spinal column. Occasionally in diseases of these organs circumscribed hypophrenic pains are present. This is quite frequently the case in disease of the liver, but is rare in disease of the pancreas, stomach and spleen. The pains in hypophrenic abscess in general follow the rules above given in accordance with its location in the various abdominal organs. Usually, however, no pain is present unless the abscess reaches the surface of the organ. This rule also applies to carcinoma and echinococcus of the liver. In recent years neurosis of the cœliac plexus has attracted considerable attention. Hoffmann thinks that this condition is characterized by the following symptom-complex: (1) Spontaneous pains originating in the upper portion of the abdomen and radiating anteriorly downward, but not reaching the genital region or the lower limbs; posteriorly they radiate towards the sacrum and often involve the gluteal region; (2) Moderate constipation, the fæces consisting of small hard masses; (3) Polyuria. Two cases are reported in illustration of typical neurosis of the cœliac plexus.

Statistical Examination of the Sequelæ of Syphilis.—M. Matthes says that the present ideas in regard to the nature and frequency of the sequelæ of syphilis are largely founded upon data which have been procured in an erroneous manner, in that patients presenting themselves in various pathological conditions have been questioned regarding a previous syphilitic infection, and such has been determined or not in many instances wholly from the history given by patients themselves. It is certain that this method of obtaining statistics is open to grave objections, and is liable to lead to false conclusions. Matthes has endeavored to clear up the subject by collating a large number of cases in which the diagnosis of syphilis had been established beyond peradventure and then in such cases ascertaining the ultimate cause of death. Accordingly he has collected 568 cases in which the symptoms of secondary syphilis had been previously established, and 130 in which tertiary manifestations of this disease had been observed. Of these 114 of the secondary and 46 of the tertiary have died and the cause of death established by autopsy. In six cases the cause of death was not thus satisfactorily ascertained. Thirty-six of the secondary and seven of the tertiary died of pulmonary tuberculosis. This seems an astonishingly large number, yet when the frequency of tuberculosis in Germany is taken into consideration it would be erroneous to conclude that syphilis predisposes to phthisis. In examining into the age of these patients at death it is seen that on the average this is younger than that given for this disease in the general mortality statistics, and hence it seems certain that in syphilitics who subsequently contract tuberculosis the course of the latter disease is shortened. Twenty of the secondary and eleven of the tertiary cases died of disease of the circulatory system. Ten of the secondary and eight of the tertiary died of apoplexy, and all but eight of these were under fifty years of age at death. Four of the secondary and one of the tertiary committed suicide. Carcinoma was the cause of death in two cases, one secondary and one tertiary. In consideration of the prevailing views, with respect to the syphilic origin of tabes, it is interesting to note that of these cases only three died of this disease, one secondary and two tertiary. Five secondary and two tertiary succumbed to paralytic dementia. The remaining causes of death are distributed among a large number of pathological conditions, none of which seem of special significance. The author next considers the entire number of syphilitics (1,570) coming within his knowledge from the standpoint of the duration of their life after contracting the disease. Taking the expectation of life as given in life insurance tables as a standard, he shows that such is somewhat shortened by the contraction of syphilis.

The Journal of Tropical Medicine, February 1, 1902.

Spirillum Fever (Relapsing or Famine Fever).—Cuthbert Christy reports on an isolated epidemic of relapsing fever in Jeur, India. He raises the question whether the bedbug, which is everywhere found in these houses, may not be the means of transmission of the disease. Using bug-traps (a piece of wood with slits in it, which is placed beneath the bed clothes at night and to which the bugs retreat in the morning), he collected a number of bugs from the beds of persons suffering from spirillum fever. The results of allowing the bugs to bite him were, however, negative. By reason of its strong chitinous exterior the bug, like the flea, is extremely difficult to dissect and examine, and the author would welcome any suggestions tending to simplify the proceeding.

On the Danger of Subcutaneous Injection of Quinine.—J. Preston Maxwell, having by experimentation found that the injection of too concentrated solutions of quinine produced gangrenous patches or cellulitis, now administers the remedy according to these principles: (1) The injection should be intramuscular, not subcutaneous; (2) The gluteal, scapular, and deltoid are the muscles best suited for this method; (3) The injection used consists of six grains of the hydrochlorate to forty minims of boiled water; this solution is brought to a boiling point and allowed to cool; the essential point is a large dilution of the acid salt; (4) After injection, which is always painful, iodine liminent is painted over the point of injection and the surrounding area. The author has never seen any untoward results from this method. He holds that injections are not absolutely safe in the case of those suffering from any form of acute septic ulceration, as there is a possibility of the area of injection being infected from within.

The Part Played by the Fleas of Rats and Mice in the Transmission of Bubonic Plague.—Bruno Galli-Valerio does not endorse Mr. Simond's theory that the plague is transmitted to man from rats and mice through the instrumentality of the fleas of these animals. The initial blebs of which Simond speaks as a point of entry by the bites of fleas have been observed in too restricted a number to be convincing that this mode of infection is the most frequent. Moreover, he says, Simond has taken no pains to find out whether the fleas that live on rats and mice are of the same species as those that live on man. From the author's experiments they do not seem to be the same. The great difficulty experienced in infecting rats by the fleas of plague-smitten rats, raises the query why it should be more frequent from rats and mice to man who is not, as a rule, attacked by mouse and rat fleas. The facility with which it is possible to arrest an epidemic of plague where the hygienic conditions are good, and isolation is properly carried out, also speaks against the theory. The question can be solved in only one way, namely by conveying to the bodies of human beings rats' and mice's fleas that have lived on plague rats.

The Journal of Tropical Medicine, February 15, 1902.

Hemorrhagic Pancreatitis in Acute Malaria.—W. G. Ross reports a fatal case in which he describes the main points of interest as follows: (1) The unusual site selected for the sporulation of the parasites; viz., the pancreas; (2) The hemorrhagic pancreatitis associated with the condition; (3) The absence of any previous symptoms of malaria; (4) The extensive invasion of the alimentary tract by the malaria parasites, and the secondary necrosis of the mucosa, though this must have been mainly due to the bacterial invasion.

Marginal Ulceration of the Gums Occurring Among Natives of East Central Africa.—Neil Macvicar describes a disease, called among the natives Chikusa, which is unpleasant and painful, although not dangerous to life. Ulceration begins at a spot on the alveolar margin of the gum, and in a few days spreads two inches or so along the gum. The ulcerated surface has an eaten-out appearance, discharges dirty pus, and is speckled with blood clots. The roots of the teeth become exposed, and the teeth loosened. The disease lasts for weeks. The cause is probably a specific microorganism, whose nature is as yet unknown. Many patients are well nourished and cleanly in the care of their teeth. A moderately strong solution of the permanganate of potash used as a wash, or applied with a camel's hair brush half a dozen times a day or more, will, in a few days, cure even the worst cases.

The Practitioner, February, 1902.

Scarlet Fever, Measles, and German Measles—Is There a Fourth Disease?—Claude B. Ker takes up the question raised by Clement Dukes as to the existence of a fourth disease, going into the differential diagnosis of the various rashes which are likely to be confounded with the three acknowledged diseases—scarlatina, measles, and rubella. These include drug rashes, septic rashes, and antitoxin rashes. The characteristics of the "fourth disease," as described by Dr. Dukes, are incubation period of nine to twenty-one days, very slight prodromata, then an eruption covering the whole body in a few hours. It is brighter than scarlatina. The throat is swollen, the conjunctivæ are pink, the glands enlarged. The temperature averages 101° F. Weighing the evidence for and against the existence of this fourth disease, the author does not consider the arguments in favor of it convincing, but thinks the matter should be further studied and discussed.

On Floating Kidney as a Cause of Obstructive Jaundice and Hepatic Colic.—J. Hutchinson says that we have the following factors to explain the occurrence of obstructive jaundice with floating kidney:—(1) Downward displacement of the third part of the duodenum, with stretching of the common bile duct; (2) Displacement of the gallbladder and sharp kinking of the cystic duct; (3) Torsion of the vertical part of the duodenum and, perhaps, even of the bile duct. Weisker's theory of traction through bands of the peritoneal investment of the right kidney connecting it with the liver, the author has not found to be substantiated by the cases he has had under observation. As to treatment, a visit to Carlsbad, with prolonged medicinal treatment, can do no good in cases in which the "biliousness" and indigestion are due solely to the presence of a floating kidney. It may further be suggested that the neurotic or hysterical temperament, which is by some attributed to the subjects of floating kidney, is not infrequently the direct result of the latter condition and of the absence of its proper surgical treatment. The number of chronic invalids would be appreciably diminished by the proper recognition of the effects of floating kidney, and the early adoption of the only satisfactory treatment—nephropexy.

American Journal of the Medical Sciences, February, 1902.

A Case of Ophthalmia Neonatorum Caused by the Diplobacillus of Morax and Axenfeld.—E. Andrade reports a case of ophthalmia rebellious to treatment by protargol instillations, boric acid washings, and nitrate of silver applications. Bacteriological examination of the conjunctival exudate showed a pure culture of the diplobacillus of Morax and Axenfeld. Knowing the almost specific action of zinc salts on this microorganism, the author prescribed sulphate of zinc in 2.5 per cent. solution, to be instilled once a day. Under this treatment the right eye was cured in eight days, the left one in twenty. The disease had lasted in all nearly three months.

Phrenic Nerve Injuries.—W. E. Shroeder and F. R. Green report a case, as well as their anatomical and experimental researches on the subject, from the results of which they conclude: (1) That the diaphragm is not an essential muscle of respiration; (2) That as the symptoms commonly described as caused by an irritation on the phrenic were absent in the operation, and in all experimental work it is safe to infer that they may have been due to something other than simple injury to the phrenic; (3) That while the diaphragm is, undoubtedly, enervated by branches from the intercostal nerves, this nerve supply [illegible] is secondary to the pleurisy; [illegible] to carry on the action of the diaphragm after a division of the phrenic; [illegible] That a [illegible] of the phrenic nerve, producing a paralysis of the left [illegible] of the [illegible] on the affected side, and atrophy of one-half of the diaphragm, might predispose to [illegible] of the lungs, or be followed by a diaphragmatic hernia; [illegible] That a division of one phrenic nerve, resulting in paralysis of one-half of the diaphragm, is not necessarily fatal.

The Changes Occurring in Striped Muscle in the Neighborhood of Malignant Tumors.—Frank P. [illegible], from his investigations, concludes that the changes produced are: [illegible] Atrophy; [illegible] Mechanical changes: [illegible] longitudinal fibrillation, [illegible] swelling, Zenker's necrosis, [illegible] proliferation, [illegible] hemorrhage, [illegible] (6) Vascular changes: endarteritis, periarteritis, hypertrophy, and hyperplasia of endothelium. [illegible] Hypertrophy. [illegible] Regeneration forms. The changes [illegible] are produced by conditions other than malignant tumors. The changes produced in muscle by invading carcinoma are more marked than those produced by sarcoma, but do not differ essentially in kind. Those produced by sarcoma are chiefly mechanical, those due to carcinoma are mechanical, nutritive, and metabolic. Evidences of these actions are more marked in the latter than in sarcoma. Carcinoma acts more as an active injurious factor, likely upon muscle than does sarcoma.

Angina Pectoris.—Beverley Robinson gives as some of the causes which act efficiently in bringing on an attack of angina: exertion, the accumulation of flatus during sleep, cold, or a cold wind and dyspepsia. Angina pectoris is not necessarily connected with any special lesion, but there may be fibrous myocarditis, fatty degeneration of the heart walls, and more or less advanced changes of the coronary arteries. Treatment depends largely on the cause, and strict attention must be given to the laws of hygiene. Nitroglycerin and nitrate of amyl, especially the latter, are particularly useful in relieving pain. Dr. B[illegible] considers erythrol tetranitrate superior to nitroglycerin. Where nitrites do not relieve, we must recur to the old stimulants and apply turpentine stupes, or a mustard leaf or poultice over the chest, or moving a hot-water bag at a temperature of 140° to 170° F., with light touches over the whole chest. We may have to give a hypodermic injection of morphine and atropine, in small or, perhaps, even in large doses. Chloroform inhalations may be needed. In marked heart failure, ether or brandy should be given hypodermically in half to drachm doses. Oxygen inhalations are useful. As to exercise great care should be used.

A New Factor in the Etiology of Malarial Fever, Indicating New Methods of Treatment.—A. F. A. King adduces arguments to prove that heat is not a factor in the etiology of malarial disease, but explains the undeniable relation between hot climates and malarial fever by eliminating the factor "heat" and substituting that of "light." Paroxysms of intermittent fever will not, as a rule, take place at night or in the dark. In places where malarial fever prevails the disease is increased by bright, sunny weather, and lessened in clouded skies. It has long been a tradition that to prevent the occurrence or recurrence of ague it is advisable to keep in the shade and avoid sunlight. The malarial parasite is a naked amœba. Red light promotes the vital activities of amœbæ, while violet or purple light restricts them. The color of the light diffused through the blood is necessarily red. The relative liability and immunity of different races of men to malarial fever depend upon the relative translucency or nontranslucency of their skin, and probably of their blood. If this etiology proven be correct, correct treatment will consist in keeping patients in the dark, or in rooms with purple or indigo windows, and clothing them in garments impenetrable to light: in the tropics white clothing, lined with purple or black. Drugs that darken the blood, or render it violet, or lessen its translucency, should be given. Quinine sulphate in solution intensifies the violet, and even renders the ultra-violet rays of the spectrum perceptible to human vision.

French Journals.

Sudden Death in Convalescence from Typhoid Fever.—Carles reports a case of convalescence from typhoid fever, in which the patient died suddenly about the twenty-third day of the disease. There were no special visceral symptoms. Preparations of the cardiac muscle were made, and the lesions therein were insignificant, and did not explain the cause of death. The query is made as to whether the condition of the cardiac ganglia would have accounted for the [illegible] accident.—*Gazette Hebdomadaire des Sciences Médicales*, February 2[illegible], 1902.

Congenital Adenomyoma of the Intestine and a Supernumerary Lobe of the Liver.—G. [illegible] reports an autopsy on an infant born before term. At a point of the small intestine on the surface opposite the mesentery was discovered a small tumor, well defined, but with no pedicle, of the size of a pea, and pinkish white in color. In the center of the growth was a canal about as large as that in the appendix of a new-born child, but which appeared to have no connection with the intestinal cavity. This cavity was covered with cylindrical epithelium, like an enormous gland of Lieberkühn. The central canal was surrounded by a large [illegible] envelope of muscular fibers. These fibers were disposed in the same plan as that seen in a transverse section of the intestine. It is uncertain whether this was a true adenomyoma or, rather, an atrophied intestinal diverticulum. The same child had a small supernumerary lobe of the liver, having a pedicle, and being the size of a small nut. It was on the upper surface of the right lobe of that organ.—*Bulletins et Mémoires de la Société Anatomique de Paris*, November, 1901.

Calcification of the Skin.—Ri[illegible]l has a patient, a woman of thirty-one years, who since the age of sixteen has had on her hands a large number of subcutaneous tumors of the size of a pea, which in some places have become confluent, and form areas as large as small nuts. This curious formation is due to the occupation of the woman, who cleaned copper with sulphuric acid. The principal characteristic of the tumors is their hardness. The skin which covers the tumors is movable, and has preserved its normal aspect. The chief seat of the growth is the palm of the hand, and the lateral aspect of the fingers. The patient can no longer work. Now and then one of the tumors becomes painful, and the skin breaks, and a chalky mass exudes. The patient was for a long time considered gouty, but histological examination of the tumors has shown no uric acid, but they are composed almost exclusively of carbonate and phosphate of lime. These concretions are surmounted by a fibrous capsule. It is a case of calcification of the skin, probably due to a dermatitis caused by the use of sulphuric acid.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, February 2[illegible], 1902.

Penetrating Wound of the Chest by a Sword; Pleuropneumonia; Persistent Fistula; Pneumotomy.—Rigal reports the case of a soldier who was wounded by a sword thrust at the level of the right axilla. There came at once from the wound a flow of frothy blood; the patient was cyanosed, and there was dyspnœa and subcutaneous emphysema. On the same day, treatment was instituted consisting of drainage and antiseptic dressings. Soon there developed pleuropneumonia with intense fever and delirium. The third day the pleural opening was enlarged, and abundant pus was found; antiseptic irrigation was practised. Little by little the fever subsided, and the general state improved. But there was a persistent fistula communicating with a pocket. The fistulous tract was judged incurable, and it was decided to stretch the tract, under anæsthesia, to resect the fourth rib to the extent of about 8 cm., and to incise the pulmonary wall with the thermocautery. From this time there was a fall in the temperature, progressive improvement followed, and a complete cure was effected forty-seven days after operation.—*Lyon Médical*, February 16, 1902.

Contribution to the Study of Ether Narcosis.—Paul Campiche concludes that: (1) Ether is a specific irritant of the lungs and bronchi, and consequently is absolutely contraindicated in all patients whose respiratory apparatus is in bad condition; (2) Even when taking cognizance of the contraindications to ether, and although the technique be as perfect as possible, the point of entire suppression of ether pneumonia has not yet been reached; (3) A certain number of accidents are inevitable, and in the use of chloroform they are undeniably more frequent than in ether narcosis; (4) The rôle of the responsibility of narcosis for pulmonary complications has been greatly exaggerated; (5) A general defective state (bad for the heart in ether, and bad for the bronchi in chloroform) is responsible for many untoward results in narcosis; (6) But in the great majority of patients there are no accidents unless the operation is particularly favorable to pulmonary complications, viz., operations for hernia, for goiter and laparotomies; (7) Ether, being less dangerous than chloroform as regards the remote consequences of narcosis (bronchitis and pneumonia), ought to be, excepting its contraindications, adapted as the anæsthetic of choice on account of its great advantages over chloroform, chief among which is its harmless effect on the heart and the circulation.—*Revue Médicale de la Suisse Romande*, February 20, 1902.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 6, 1902.

Robert F. Weir, M.D., President.

The Use of the X-Ray in the Treatment of Some Forms of Cancer.—Dr. Francis H. Williams of Boston, Mass., was the author of the paper of the evening, and the meeting was held under the auspices of the Section on Surgery. Dr. Williams said that either a good-sized static machine or a coil was required for this work. He used at the hospital a static machine of eight plates, of very large size, while he employed a coil at his office. There should be an adjustable spark gap, and the tube should be carefully selected for this special work For superficial growths tubes of low resistance should be used, and for deeper growths tubes of high resistance. The tube should be placed in a holder, the inside of which is painted with white lead. By means of a lead screen the cone of rays is limited to a size a little larger than the diseased area to be treated. For use in cavities, such as the mouth or the vagina, it was recommended that the rays be passed through a cylindrical glass speculum, the latter being surrounded by a shield of sheet tin. As a general rule, the diseased area should have an exposure of five or ten minutes at each sitting, and this time may be gradually increased to twenty minutes or more. The exposures should be given three or more times a week. The actively-growing tumors should receive very short exposures at first, probably not more than five minutes. Itching, prickling, a drawing sensation or a slight irritation in the new growth a day or two after the exposure should be looked upon as a favorable sign. The sound tissues were not affected by the exposures required for this treatment. If the exposure were properly timed it would not cause any reaction in the recently healed portion, though it would have done so in the same part before healing took place. The speaker deprecated the tendency in some quarters to relegate this important work to non-medical persons. During the past six years, he said, thousands of exposures had been made at the Boston City Hospital for examinations and treatment, and no one had ever been burned by the *x*-rays there, showing that no harm need result from their use. Dr. Williams said that a microscopical diagnosis had been made for him in almost all of his cases. The growths which he had subjected to this treatment included epithelioma, rodent ulcer, carcinoma, papilloma of the larynx, spindle-cell sarcoma, keratosis, new growths looking clinically like epitheliomata of the lip, but appearing under the microscope as inflammatory tissue, etc. The growths had been on all parts of the face, on the ear, tongue, jaw, neck, larynx, arm and breast, as well as in more deeply-situated parts. It seemed probable that most cases belonging to the external class could be made to disappear by means of treatment with the *x*-rays if treatment were commenced sufficiently early. Thus far every case of external new growth that had come under his care early was healing or improving. In the more advanced cases the choice of operation and the *x*-ray treatment would come up. The latter was tedious, and as yet experience with it was limited, though rapidly growing. In a third group might be placed the cases which are inoperable, or those in which the patient declines operation. While operation might be advised in certain cases, there need be no hesitation about using the *x*-rays where this treatment afforded the only chance, as it would usually give relief, to say nothing of encouragement to the patient. It should be remembered that a short period of treatment would suffice to show whether the *x*-rays could effect improvement. Thus, in epitheliomata such improvement would usually be evident in about two weeks. The fact was emphasized that it was not a good plan to operate first and then use the *x*-rays, because after even a slight operation the *x*-rays experienced difficulty in favorably affecting the tissues. All of his cases of rodent ulcer were slowly improving or had healed with one exception. The exception was a case of an old woman, living at a distance, who had shown temporary improvement, but had been unable to come for regular and effective treatment. Some of his cases had been healed for more than a year, and there had only been one recurrence. This had occurred, after about six months, in an epithelioma of the lip. The recurrence yielded readily to treatment. Some cancers of the tongue that he had treated had been difficult of access, and had improved, but had eventually become worse. The speaker said he believed that the *x*-rays would prove beneficial in certain forms of cancer of the breast. Carcinoma would yield more readily to this treatment than would the scirrhus variety. Growths reappearing in the scars following operation had ceased to spread, and had shrunken up and fallen off. Dr. Williams exhibited a number of photographic lantern slides to show the results obtained from the *x*-ray treatment. In a case of Hodgkin's disease the improvement effected by one exposure was very striking. The advantages of the *x*-ray treatment were the absence of any dread of operation, the painlessness of the treatment and the excellence of the cosmetic effect. At present a practitioner was not justified in promising that the *x*-ray would cause deep-seated growths to heal. It might, however, give relief in operative cases. Most superficial or early external new growths would yield to this treatment, and the condition could usually be ameliorated in more advanced external new growths. As soon as it was widely known that there was a harmless, painless and excellent method of treating external new growths, the people would resort to it earlier than they now come under treatment, but the profession should warn them of the present narrow limitations of the method.

Dr. William James Morton said that nothing that could be said on this subject at the present time could be looked upon as more than a report of progress, but this progress was real and rapid. He would admit that he found it difficult to speak so dispassionately and so judicially on this new and most interesting topic as had the reader of the paper. He agreed with that gentleman that it made no difference what form of apparatus was employed, provided it produced a good *x*-ray. He did not think any extended treatment could be satisfactorily conducted without employing one of the self-regulating tubes. In certain matters of technique he would differ from the author. One of these was in the use of the aluminum screen, even though it had the authority of Tesla behind it. This screen was very troublesome, and he did not see that it accomplished anything of importance. It certainly cut off the electrostatic field, but after all this was of no consequence, for it was not the electricity that caused burns. Nor had he seen any advantage in insulating the lead plates, and therefore he made use of ordinary tin foil. The quality of the *x*-ray was most important, and yet he could not speak very definitely on this point. He would divide *x*-ray tubes, as regards their quality, into three classes: soft, medium soft and hard tubes. The medium soft and the hard tubes were chiefly used by him. According to his experience, sarcomata were the easiest to deal with. Next to these came the carcinomata, while the most difficult of all were the epitheliomata. His *x*-ray work had taught him a new classification based upon what the *x*-rays could do. He divided his cases as they came to him into: (1) Exterior or superficial cases; (2) Interior cases, or those beneath a healthy skin; (3) Operable cases, and (4) Inoperable cases. For the first class a medium soft or a soft tube should be used; it would break down the growth better than would a high tube. In the treatment of the interior cases one was met at the outset with a serious obstacle, the inter-

[illegible] healthy skin, which has to be protected from the development of a dermatitis. Assuming that general metastases would occur in from six to twelve weeks, the x-ray operator was confronted with a more serious problem, and at the present time he did not feel like assuming the responsibility of advising the use of the x-ray in preference to the knife in operable cases. He had found carcinoma of the breast, both initial and recurrent, yield well to the x-ray treatment. In one inoperable case of very extensive carcinoma of the breast after ten weeks of treatment with the x-ray, the induration had practically all disappeared, the pain had been relieved, and the carcinoma had been reduced from six inches in diameter to a mass measuring 1½ by 2½ inches. Another case of carcinoma of the breast had been referred to him by Dr. W. B. Coley after Dr. Buxton had made the diagnosis of carcinoma of the breast by microscopical examination. The case had been operated upon three times, and this was the fourth recurrence, appearing in the form of a nodule situated near the junction of the third rib with the sternum. After treatment with the x-ray for three weeks this nodule had disappeared, and, as only three weeks had elapsed since this disappearance, nothing could be said as to the permanence of the cure. Dr. Morton concluded by exhibiting a young woman who had a large osteosarcoma behind the right ear and a considerable tumefaction in front of the ear. Treatment had been begun about one month ago with the x-ray, at which time the ear was in a shapeless state, involved in a very large tumor. She had received twenty treatments with the x-ray, and, while she had not been burned, her face had been very markedly tanned. About nine-tenths of the tumor had already disappeared, and the patient from the outset had been able to give up the morphine which she had been using quite freely on first coming under observation. He expected to cause a complete disappearance of the growth in about ten days more.

Dr. A. B. Johnson said that his experience in this field had been quite limited, but had included inoperable carcinomata, many of the recurrent variety. He had generated the x-ray by means of a coil, and the tubes employed had been those which would permit of using a large amount of energy. These tubes were large, and were artificially cooled by ice water. His first case had been exposed thirty-two times, the tube being at a distance varying from ten to four inches. The exposures had averaged about ten minutes. The patient was a lady who had had two operations for cancer of the breast. These operations had been followed by a recurrence, consisting of an ulcerated growth, four inches long and three inches wide, firmly adherent to the ribs, together with several hundred secondary nodules scattered over the skin of the thorax, the upper part of the abdomen and the opposite breast. There were enlarged lymphatics in both axillæ, and there were some nodules on the back. Without burning this woman the large growth had been made to practically disappear, the only trace now remaining of the large mass being an area resembling that seen after skin grafting. Another case, one of carcinoma of the jaw, had been a most unfavorable one. There had already been an extensive plastic operation for epithelioma of the lip. It involved nearly all of the ramus of the jaw. The patient had been exposed about twenty-five times to the x-rays, and with very marked benefit. The size of the tumor and of the surrounding soft parts was much less, and the neighboring lymph glands had diminished in size. The man's general health had decidedly improved, and from some of the sinuses which still remained open there was a discharge of what appeared to be broken-down carcinoma. Another case, one of ulcerating epithelioma of the ear, had also been benefited. After two exposures the bleeding had ceased absolutely, and after four exposures the ulcerated area became a healthy granulating surface. The speaker said that he was of the opinion that by the use of more powerful apparatus it would be possible in the future to attack the more deeply seated new growths with a fair chance of success.

Dr. William B. Coley said that his experience with the x-ray treatment extended only over a period of four weeks. At the present time he had under treatment six cases of sarcoma at the General Memorial Hospital. The first was a round-cell sarcoma in a man of twenty-five, and had been first noticed in the parotid region last September. It had grown rapidly, and had recurred soon after operation. When first seen last January Dr. Coley tied the carotid artery and gave him the toxins without apparent benefit. He was then treated with the x-rays, using a high vacuum tube, placed at a distance of six inches. The man steadily failed and was now in a dying condition. Another case was one of large inoperable recurrent sarcoma of the spindle-cell variety, situated in the maxillary region. The patient had improved so rapidly at one time under the toxins that he was thought to be almost cured, but progress had then ceased, and accordingly the x-ray treatment was begun. So far there had been no marked change. Another case, one of sarcoma of the thigh, of very rapid growth, had continued to increase despite the use of the x-rays. A boy having a sarcoma of the thigh and refusing operation had been subjected to the x-ray treatment, and already there had been very marked improvement. A case of very extensive lymphosarcoma involving both sides of the neck and the neighboring lymphatic glands had been treated with the toxins without benefit, and three weeks ago had been subjected to the x-ray treatment. The improvement in this case had been little short of marvelous. Dr. Coley presented also a patient with a remarkable history. Ten years ago he had been operated upon at the New York Hospital for a typical round-cell sarcoma of the neck. Its nature was determined at the time by microscopical examination. In 1896 two recurrent tumors had been removed, and these were found to be small round-cell sarcomata. In all he had been operated upon five times, and seven tumors had been removed. His case was considered inoperable at the Vanderbilt Clinic last May, and he then came to Dr. Coley for the toxin treatment. He received twelve injections, and the external carotid artery was tied, but with apparently no controlling effect upon the disease. He left the hospital last July with a tumor about the size of the closed fist. On December 22 he came under the care of Dr. E. R. Fisk of Brooklyn, and at the urgent request of the patient he was given the x-ray treatment. For the first two weeks he received daily treatments of ten minutes each, and for the next two weeks daily treatments of fifteen minutes each. After that he received treatment at longer intervals. The improvement that had taken place was most remarkable, and the case was particularly interesting because of the complete record accompanying it.

Dr. Charles W. Allen said that he believed the x-ray was capable of doing a large amount of good, and hence he had recently begun its use in his practice, but in doing so he had not felt warranted in using the x-rays to the exclusion of other recognized methods of treatment. He had treated fifteen cases in all, and had the records of six cases which he believed to be cured epitheliomata, but which, of course, he would not report as such at this time. Dr. Allen exhibited a case of lupus of twenty-four years' duration that had apparently been cured by the x-ray treatment. One of his cases was an extensive rodent ulcer of five years' standing. After the very first exposure to the x-rays the whole area had presented an appearance quite like that seen in a vaccination. He had almost invariably noted a cessation of pain after the application of the x-rays. Dr. Allen also exhibited a device for facilitating the application of the x-rays by providing for the easy adjustment of the screen and tube.

Dr. **Percy Turnure** presented two patients. The first was a case of epithelioma occurring in a man of sixty years. Photographs showing his condition last December were exhibited. At that time Dr. Bull had examined the man at Roosevelt Hospital and considered the case to be inoperable. The *x*-ray treatment was begun on December 18, and exposures of five minutes were given three times a week up to January 20, and then he received daily exposures of ten minutes for one week. By that time the ulcer had broken down and there was free discharge, so the treatment was discontinued. The glands had entirely disappeared, and the case was practically cured. The second case was that of a woman in whom a red spot had appeared on the nose eighteen years ago. Two years later a similar spot had appeared on the other side of the face. All sorts of treatment had been tried since that time. The case had been sent to him by Dr. C. T. Dade, with a diagnosis of erythematous lupus. The *x*-ray treatment had been begun on December 2, and had been continued three times a week until January 18, when daily treatments had been given for a short time. The course of the case was practically the same as that of the first one. During this treatment for lupus what was apparently an epithelioma had developed in the middle of the right cheek. Its gross appearance was typical of a beginning epithelioma, but the microscopical examination only indicated the probability of its being epitheliomatous. The speaker said that his results had been most discouraging in carcinomata.

Dr. **George C. Hopkins** of Brooklyn said that he would disagree with Dr. Williams entirely in the use of the screen. He had treated a large number of cases, and had never yet had an *x*-ray burn. The *x*-ray does not seem to affect the skin as it does the deeper tissues. His researches with regard to white gangrene indicated that the trouble began in the deeper tissues and spread toward the surface. It seemed to him entirely possible to be able to treat the deeper tissues successfully with the *x*-rays. His work with these rays had been largely in the treatment of recurrences after operation, and in this class of cases the results had been most satisfactory. In one of these cases there was a cicatrix fourteen inches long, on which were seven ulcerating nodules. Under the influence of the *x*-rays five of these nodules had disappeared, and the corresponding areas were healed. He expected to have the other two nodules healed very soon. In another case, supposed to be one of carcinoma of the tongue, demanding immediate operation, three weeks of *x*-ray treatment had restored the patient's speech and had made it possible for him to again eat solid food. The speaker said that two years and a half ago he had begun to use the coil and his results had not been satisfactory. More recently he had used the static machine and a low vacuum tube, and he thought with this outfit there was very little danger of causing *x*-ray burns.

Dr. **H. G. Piffard** narrated a case of epithelioma of the cheek, which would have taken two months of treatment with the *x*-ray, he said, whereas he had cured it in a very short time, and at much less expense to the patient, by curetting and the subsequent application of the galvano-cautery. He saw no occasion theoretically for the use of the screen.

Dr. **Williams** closed the discussion. He said that it was quite possible to get a dermatitis even when a screen was used; on the other hand, it was quite possible to get a severe burn from the brush discharge, and hence it seemed to him the part of prudence to make use of the screen, and so diminish the risks of the treatment. For the treatment of cavities he thought a speculum of glass was better than one of metal, because it was a non-conductor of electricity.

NEW YORK ACADEMY OF MEDICINE.

Section on Obstetrics and Gynæcology.

Stated Meeting, Held February 27, 1902.

James N. West, M.D., Chairman.

A Case of Cæsarian Section for Rachitic Pelvis.—Dr. L. J. **Ladinski** presented a woman, twenty-seven years of age, who had been married five years. At two previous confinements she had been delivered by craniotomy. She came under his observation about two weeks prior to delivery, and after examination of the pelvis he had come to the conclusion that at this advanced stage of pregnancy the only chance of a living child being delivered was by Cæsarian section. The Porro operation was advised but refused. The measurements of the pelvis were: Between the iliac spines, 27 cm.; between the iliac crests, 28.5 cm.; external conjugate, 16.75 cm.; internal diagonal, 10.5 cm. The measurements of the child made after delivery were: Occipito-mental, 14 cm.; occipito-frontal, 13 cm.; occipito-bregmatic, 12 cm.; biparietal, 10 cm. The membranes ruptured during the night, and the patient was in labor for thirty-six hours before the operation was done. The uterus was drawn outside of the abdominal cavity, incised, and the child delivered without applying a ligature because of the œdematous state of the uterus. The placenta was attached anteriorly, so that it was necessary to remove the child through it. This was done very rapidly, without much hemorrhage. Mother and baby left the hospital in good condition.

Dr. **S. Marx** said that from his examination of the patient the case was evidently one of the flat rachitic pelvis. The measurement between the anterior spines was 28 cm., that between the crests 28 cm., the external conjugate 17 cm., and the estimated true conjugate 7.25 cm. On examination externally there was noted a well-marked curvature of the lumbar spine anteriorly, from which it was probable that there was a spondylolisthetic pelvis. An experience that he had had within the past twenty-four hours showed that no pelvis was a distinct indication for Cæsarian section. At the first confinement, the woman referred to had been delivered of a dead child after an extremely difficult version. At the second confinement the family physician had delivered with forceps a child which was so maimed that it died in a very short time. Last night he had been called to see her, and from the measurements of the pelvis had felt justified in urging Cæsarian section. The mother refused this, and to his surprise he had been able to easily deliver a living child by version with the woman in the Walcher position.

Dr. **W. R. Pryor** said that in a case of Cæsarian section in which he had met with implantation of the placenta anteriorly, he had found no difficulty in the operation because he had taken the precaution to make a free incision through the muscular portion of the uterus before coming down upon the placenta.

Dr. **Philander A. Harris** remarked that, in certain instances, the pelvis might be 8 or even 7.5 cm., and still, by reason of the smallness of the fœtus, delivery could be effected.

Carcinoma of the Uterus.—Dr. J. A. **Schmitt** presented this specimen, which had been taken from a woman whose menstruation had ceased six years previously. She sought advice because of a sero-sanguineous discharge from the uterus. The presence of a polyp projecting from the os suggested a good prognosis, but further examination showed evidence of carcinoma. In all doubtful cases scrapings from the uterus should be examined microscopically.

Dr. **H. J. Boldt** remarked that microscopical examination should be invariably made of scrapings from the uterus.

Dr. **Pryor** said that when the microscopical examination revealed distinct evidence of malignant disease, such a confirmation of the diagnosis was very gratifying, but in doubtful cases he would rather depend upon the results of uterine curettings, as a negative microscopical examination in such cases was utterly valueless.

Dr. J. Riddle Goffe said that his experience would lead him to take the same view as Dr. Frank. He recalled one case in which curettings were examined microscopically, at intervals for four years, and during all this time the report of the pathologist was negative. The uterus was then removed, and it presented abundant evidence of malignant disease.

Dr. Joseph Brettauer said that he was a thorough believer in the value of microscopical examinations of material curetted from such cases, but he failed to see the necessity for examining microscopically all curettings from the uterus.

Dr. S. W. Bandler said that the pathologist might be criticised for calling something else carcinoma, but he should not overlook carcinoma when present. The examination of two or three pieces of tissue removed by the curette was not a thorough examination, a true thorough examination involved embedding and examining the large number of pieces removed by curettage, and this was a task requiring about ten days of hard work.

Dr. [illegible], in closing, called attention to the error that would be likely to arise from the operator not being careful to systematically curette all portions of the uterine cavity.

Dr. H. J. Boldt presented the following specimens:

Intraligamentous Fibromyoma Completely Separated from the Uterus.—Regarding this specimen, he said that intraligamentous tumors of this structure could almost invariably be shown to arise from one of the lateral borders of the uterus and, inasmuch as they develop laterally, the connection between the uterus and the neoplasm frequently became quite thin, so that, in some instances, it might be difficult to ascertain whether the tumor was primarily of uterine origin, or whether it took its origin from the muscular structure in the broad ligament. In this instance, the difficulty was increased by the fact that the separation between the tumor and the uterus was complete. As the interval was about 1.5 cm., he was inclined to believe that the neoplasm originated from the muscular structure in the broad ligament.

Retroperitoneal Fibromyoma of the Uterus; Abdominal Hysterectomy. The tumor filled the true pelvis completely, producing pressure symptoms. An interesting feature was the existence of intense trachycardia, the pulse rate varying from 120 to 140. As the trachycardia had subsided since the operation, it must be looked upon as a reflex vasomotor neurosis caused by the tumor compressing the pelvic organs. From a pathological viewpoint, the tumor was interesting. The greater part of the pedicle was inserted at the lower segment of the posterior surface of the uterus, and about one-third of the thick pedicle was given off from the cervix. As the result of this, all of the tumor except the summit had developed retroperitoneally. The enucleation of the neoplasm proved to be an arduous task, the oozing from the bed being so profuse that it was necessary to suture it before replacing the peritoneum upon it.

Uterine Adnexæ Removed for Recurrent Pelvic Inflammation.—The patient was a woman of thirty-five years who had had numerous attacks of pelvic inflammation during a period of twelve years. For five years prior to operation she had seldom had a day during which she had not had more or less pelvic pain. The tubes and ovaries presented the characteristic changes usually seen in chronic inflammation of the appendages, the walls of the tubes being much thickened as the result of interstitial inflammation. There was found an unusually large hydatid of Morgagni. The vermiform appendix was thickened, especially at its distal extremity. He inverted it according to the method described by Edebohls. Since the operation the patient had had very little pain, and what remained would undoubtedly soon disappear. When a patient had been ill a number of years with pelvic inflammation, and the ailment had withstood the various forms of treatment usually adopted for such conditions, it was not good therapy to continue with local treatment if the cause of the trouble was apparently disease of the adnexa. In such cases surgical intervention should be resorted to, as the health of these patients was undermined more and more by waiting, and prolonged local treatment had a tendency to produce a neurasthenic condition which was very difficult to eradicate.

Chronic Unilateral Salpingo-Oophoritis, Probably Caused by Appendicitis.—This specimen had been removed from a woman who had suffered from pain in the cæcal and the corresponding ovarian region for several years. Pressure on the right side caused such pain, so that palpation was unsatisfactory. Bimanual examination showed the right half of the pelvis to be filled with a mass consisting of the enlarged tube and ovary. The latter seemed to be cystic, but the tube felt very firm to the examining finger. The left tube and ovary appeared to be normal. The uterus was somewhat enlarged and its consistency was firmer than normal. On abdominal section the vermiform appendix was found to be chronically inflamed and in close proximity to the tube. He inverted it into the cæcum and removed the adnexa. The left adnexa was normal. The lumen of the tube was practically obliterated throughout its entire length and the wall of the tube was hypertrophied to fully four times its normal thickness. The ovary was degenerated to such an extent that only a small part of the ovarian stroma remained, and that was near the cortex. The specimen was an excellent example of chronic inflammation, with an unusual degree of hypertrophy of the oviduct wall. That the appendicitis was the probable exciting cause of the adnexal inflammation seemed evident from the history, the close relation of the appendix to the diseased appendage, and from the fact that the opposite appendage was normal.

Bilateral Hæmatosalpinx; Hæmatoma of the Ovary.—This patient had been a sufferer from intense pelvic pain since her marriage three years previously, and had never been pregnant. The pelvic organs were exquisitely tender and the Fallopian tubes distended and adherent. Abdominal section revealed a small quantity of blood in the peritoneal cavity, and both Fallopian tubes distended and intimately adherent to the surrounding tissues. It was found possible to remove the tube on the left side without the ovary, and the latter was attached to the uterus to preserve the menstrual function. Inspection of the specimens showed the hæmatosalpinges situated in the abdominal half of the Fallopian tubes, and the uterine ends of the tubes occluded. The cause of the blood accumulation in this instance, Dr. Boldt believed, was torsion from peritoneal adhesions. The existence of hæmatosalpinx could not be diagnosed in such patients, but the indication for operation was the persistence of pelvic pain. It was customary to consider tubal gestation as the most frequent cause of hæmatosalpinx, but he was opposed to such definition when the accumulation of blood was caused by pregnancy in the tube. The most serious, if not the only serious, form of hæmatosalpinx was that caused by gynatresia, inasmuch as it was liable to rupture and cause fatal peritonitis. But when the etiology was that found in the present case, there was little danger of rupture from over-distension of the tube, and in such instances operation was undertaken because of the symptoms resulting from the pelvic inflammation.

Dr. P. A. Harris said that he had removed two tumors of about the same size as those just presented, and attended by considerable hemorrhage. He would present them at the first opportunity.

Dr. Brettauer said that he did not think Dr. Boldt had adduced sufficient proof that the first tumors were truly intraligamentous. It was more probable that they had originally developed from the uterus extraperitoneally and had subsequently become separated from the uterus. He had seen several fibroids which were apparently both extraperitoneal and intraperitoneal. One was sometimes deceived in these cases by an unusual development of the mesentery of the sigmoid flexure. He could not understand how a tumor could be both intraperitoneal and extraperitoneal at the same time.

Dr. J. Riddle Goffe thought we were apt to exaggerate the influence of the vermiform appendix on disease of the uterine appendages, as in one of the cases now under discussion.

Dr. G. H. Balleray said that he had never operated upon more than three cases of true hæmatosalpinx, but in these no evidence of ectopic gestation could be found. In such a case the tube was not adherent and contained considerable bloody fluid. He was under the impression that a secretion took place from the lining membrane of the tube, a condition similar to the weeping from the uterus and tube during menstruation. He did not think that true hæmatosalpinx had anything to do with ectopic gestation.

Dr. Marx said that he had removed quite a number of intraligamentous fibroids, which he believed had absolutely originated *de novo* between the layers of the broad ligament.

Dr. Boldt said that he realized that a positive diagnosis of intraligamentous fibroid could not be made in his case, but the appearances pointed that way. He was of the opinion that a true hæmatosalpinx was never caused by tubal gestation, although many statements in the text-books seemed to indicate such a view.

Dr. Bandler said that there had been reported in the literature cases of tumors of the broad ligament containing glandular epithelium derived from the Wolffian body, and when this was the case the tumor had originated *de novo* between the folds of the broad ligament.

Ovarian Pregnancy with Viable Fœtus.—Dr. W. R. Pryor reported this case. At the operation it was found that the colon hid a large part of the cyst. A fœtus of about six months was delivered. It cried and gasped a few times and then died. Conception had apparently taken place in the Graffian follicle over which the tube was adherent. In its growth it had separated the folds of the broad ligament, lifting up the ureter.

Dr. Boldt did not think that one could arrive at a conclusion as to the nature of such a pregnancy from the gross appearances alone. He remembered one case which he had taken to be an abdominal pregnancy, but prolonged and careful search had shown it to have been originally a tubal pregnancy.

Dr. Goffe said he was disposed to accept absolutely Lawson Tait's description of these ectopic pregnancies, and was of the opinion that they invariably began in the tube. Of course, true ovarian pregnancy must occur in the Graffian follicle, and it was rather difficult to believe that the spermatozoa came into contact with the ovum at this point. It was more probable that the pregnancy had occurred originally in the tube, and had ruptured into the broad ligament.

Dr. Brettauer said that he had been present at Dr. Pryor's operation on this case, and could testify that the tube was absolutely intact. He felt positive that it never started as a tubal pregnancy. Microscopical examination of the wall of the sac and of the placental site was essential to a proper understanding of this case. His recollection was that the placenta was attached within the tumor.

Dr. Pryor said that, according to Welch, the sac in this case was made up of the spread-out ovary, and he had never seen the ovary spread out eight inches in a tubal pregnancy. The placenta was certainly within the sac. The Fallopian tube ran entirely over the top of the tumor, the tube standing out just as it did in a parovarian cyst. Dr. Welch said that because of the extreme rarity of ovarian pregnancy he was not willing to make that diagnosis, but he would not dispute the possibility of this case being an example of such a form of pregnancy.

Hypertrophies of the Labia Minora.—Dr. R. L. Dickinson presented, in a paper with this title, a preliminary report of observations made by him extending over a period of fifteen years, though the greater part of the material utilized in the paper had been gathered during the last seven years. The type or full development of the deformity in question, he said, was a wrinkled and pigmented enlargement of the labia minora, the lesser labia protuding through the labia majora. One labium was usually larger than its fellow, and the prepuce often participated in these changes. Distinctive increase in the size of the clitoris, contrary to the general belief, was rare. Enlargement of the breasts and changes in the areolæ resembling those of pregnancy occurred. The most marked cases occurred in women who had never borne children and who possessed a hymen indicative of virginity. In a series of 1,000 consecutive gynecological cases, 361, or more than one in three, showed one or more of the various vulvular hypertrophies considered in the paper. In the blonde the enlargement of the labia was not so characteristic, though large blue veins were more readily identified and the follicles were frequently large and white. The speaker was of the opinion that all large, deeply-wrinkled labia minora indicate prolonged massage. This massage might be applied by crossing of the legs and pressure on the labia minora rather than upon the clitoris. The speaker said he had seen at least a dozen of noniparous women having an exceedingly elastic and dilatable hymen, one perhaps distensible to eight or nine inches, a condition characteristic of vaginal massage. Dr. Dickinson said that in the growing girl the nervous system might be very seriously affected by masturbation, and hence any means of detecting such practices should be of value to the physician. A sufficient number of his patients had admitted such practices to justify him in the belief that others presenting the same signs, though not confessing to masturbation, had been guilty of similar doings. It should be noted that in a great many women masturbation was not what might be called a strictly sexual act, but rather a physical matter; in other words, many of the most refined and lovely women suffer from tormenting excitement of the nervous system, which they learn to relieve in this way. Sometimes by removing adhesions of the clitoris, or by circumcision, great relief was afforded such persons.

Dr. Brettauer recalled the case of a girl of fourteen who suffered so much on the second day of each menstrual period that she finally sought advice and relief. Examination showed exceedingly marked hypertrophy of the labia minora. However, from his own observations he had been led to look upon these changes in the labia as largely a racial matter. He had seen a great many more of these hypertrophies among Russian and Hebrew women than among Germans, and he had found these hypertrophies quite exceptional among American women.

Dr. Pryor said that he had many Syrians in his dispensary practice, and had noted among them frequent enlargement of the labia minora. These women were very cleanly about their persons, and followed the Mohammedan practice of clipping the hair short about the genitals. The same hypertrophies were frequently noted among negresses.

Dr. Balleray said that he thought Dr. Dickinson's experience must be quite exceptional, because a proportion of one in three hardly represented the frequency with which these conditions were encountered by the average gynecologist. This might perhaps be explained by his having seen a large number of women of a certain race. The profession was certainly indebted to Dr. Dickinson for calling attention to these changes.

Dr. Dickinson, in closing the discussion, said that the racial question was an interesting one. It had been proved that among the Hottentots the enormous development of the labia minora into an "apron" was brought about by the custom of making traction on these parts during the period of a [illegible] growth. He mentioned that the enlargement of the [illegible] had not been found to be especially frequent among the [illegible] of our Southern States, though it was more common as a general rule in proportion to the [illegible] of the people. There were many cases of [illegible] and [illegible] though [illegible] would be found in the [illegible] no such [illegible]. If however there were [illegible] changes about the [illegible] it was fair to assume that the pain was the result of [illegible]. The patient would [illegible] about the [illegible], but if the treatment were [illegible] to the [illegible] of [illegible] the patient would [illegible].

THE PRACTITIONERS' SOCIETY.

Stated Meeting, Held on Friday, February 7, 1902.

HENRY F. WALKER, M.D., President, *in the Chair.*

A Case of Pulmonary Osteoarthropathy.—Presented by Dr. WALTER B. JAMES. The patient was a man twenty-seven years old who had enjoyed good health until about three years ago, when, without known cause, he began to suffer from a cough. Soon after the onset of this cough it became paroxysmal in character, accompanied by a feeling of distress and suffocation, and these paroxysms were finally relieved by the expectoration of several ounces of purulent sputum. After these symptoms had continued for several months, he began to complain of pain in the hands, especially in the bones of the wrist, and in the ends of the long bones of the legs. He also gave a vague history of irregular fever, chills, and sweating.

The patient was first seen by Dr. James six weeks ago. He still complained of these paroxysms of coughing, with free purulent expectoration. His sputum was examined, and found to contain a large number of streptococci and colon bacilli, but no tubercle bacilli. Inoculation experiments in guinea pigs gave negative results. A physical examination revealed a general bronchitis, with coarse, sticky rales over the base of both lungs. The man's temperature usually ranged between 99 and 100° F., then suddenly he would have a chill, followed by a temperature of 103° or 104°, which would again rapidly fall to the normal or slightly above. These chills and temperature elevations occurred at irregular intervals, and were not limited to any definite time of the day, but they were more apt to occur soon after an unusually severe paroxysm of coughing, and after the lung had been relieved of a collection of purulent sputum.

Some time subsequent to the onset of the pain in the bones, changes were first noticed in the ends of the bones. They became thickened, the ends of the fingers showed the typical club-shape, with fluctuation at the base of the nail. These changes in the ends of the bones have steadily progressed. A number of radiographs were exhibited by Dr. James which clearly showed the deposits of new bone and the fact that the clubbing of the finger tips was due entirely to thickening of the soft parts.

The physical signs in this case are so vague in character that the speaker said he had not been able to locate positively the seat of the chief difficulty. The patient had been given carbonate of creosote and creosote by inhalation, and latterly, intratracheal injections of menthol in olive oil. No malarial organisms have been found in the blood, and the spleen is not enlarged. In the lower dorsal and upper lumbar region the spines of the vertebræ are wanting, and these bones are very tender to pressure.

The case was clearly one of chronic fetid bronchitis, with dilatations of the bronchi, and with the pulmonary osteoarthropathy which occasionally complicates the condition.

The negative result of inoculation of the sputum into guinea pigs may be regarded as excluding tuberculosis.

Interesting and unusual features are, first, the irregular attacks of high fever and chills without [illegible] and without any evidence of malaria, and, second, the very severe pain which [illegible] the paroxysms of coughing and limited to the [illegible] and the parts of the long bones which are changed, these pains being a very early phenomenon and perhaps antedating the bone lesions.

Dr. V. P. GIBNEY said he had seen a few cases of pulmonary osteoarthropathy, but had never had an opportunity to find out just what the lesion in the bones consisted of. In Dr. James' case the pulmonary condition was apparently not tuberculous in character. The speaker said that the cases with which he was familiar were in children with deformed spines, the deformity pressing on the lungs and producing changes in the chest wall. The interference with the pulmonary circulation in time produced these changes in the ends of the bones. In all his cases, Dr. Gibney said, there were distinct evidences of tuberculosis. In one case after the general health improved under better hygienic conditions, there was a distinct recession in the size of the clubbed fingers.

Dr. GEORGE L. PEABODY referred to a case of osteoarthropathy which he saw very recently at the New York Hospital. The patient was a man who was suffering from fibroid phthisis. His sputum contained tubercle bacilli. The deformity of the ends of the fingers was quite characteristic, but the toes were not affected, and there was no deformity of the long bones. The patient did not complain of any pain in the bones.

Dr. E. G. JANEWAY said that a very complete article upon this subject could be found in the transactions of the London Pathological Society for 1896. It included a history of the post-mortem findings and pictures of the enlarged bones.

Dr. GEORGE L. PEABODY said that in the last edition of Osler's work Thayer has tabulated all the cases reported up to the present time, about fifty-five in all. The large majority of these cases were tubercular.

Dr. JANEWAY said there were other etiological factors beside tuberculosis, for example, syphilis and chronic diarrhœa.

Spontaneous Venous Thrombosis from Fluorine Poisoning; Recovery: With Method of Determination of the Rapidity of Coagulation. By FRITZ SCHWYZER, M.D. (This paper will appear later.)

Dr. T. MITCHELL PRUDDEN asked Dr. Schwyzer what he had found to be the average time for the clotting of normal human blood?

Dr. SCHWYZER replied that it took from five to eight minutes. In the normal rabbit it took from six to ten minutes, sometimes only five minutes, while in most of the rabbits poisoned by fluorine clotting occurred in from one to two minutes; in one or two of them, however, three or four minutes elapsed. Dr. Schwyzer said that in performing these tests, the cleansing and drying of the capillary tubes were very important. If the least moisture or acidity is present the value of the test is interfered with.

In reply to a question as to whether fluorine salt has been used for other purposes than for the preservation of beer, the speaker replied that he understood it was also used as a preservative for canned vegetables.

Specific Medication.—By ANDREW H. SMITH, M.D. (Vide page 401.)

Dr. JANEWAY said that while he was fully in accord with those who would try the value of new drugs and new methods in the treatment of disease, and while it was well to be hopeful and optimistic, we must not permit ourselves to place too great a reliance upon the value of statistics. They are not infrequently collected by men whose judgment has been warped by their enthusiasm, and they are apt to cut out bad cases for reasons which are satisfactory to themselves, and as a result their figures show only the favorable side. Many years ago, the speaker said, he treated twenty-one consecutive cases of pneumonia at Bellevue Hospital in the most casual manner, and of those patients twenty got well. He had never seen nor heard of any better results than this by any other plan of treatment.

As regards the value of carbonate creosote in pneumonia, Dr. Janeway mentioned three cases where the drug was used without apparent effect. In one, an ulcerative endocarditis followed the pneumonia; in the second, the opposite lung became involved in spite of the fact that carbonate creosote had been given from the very onset of the disease, and in the third the patient died in spite of large doses of the drug. If we read the history of pneumonia we will find that various methods of treatment have become popular from time to time and highly praised, only to be discarded after a sufficiently large series of cases have been compiled.

Dr. Beverley Robinson referred to the erroneous idea entertained by many laymen that physicians possess a specific for every ill, and many do not take kindly to rational and intelligent methods of treatment. As a matter of fact, our knowledge of drugs is largely empirical, even of those upon the action of which we can rely. Take antitoxin, for example; we do not know whether it neutralizes the poison of diphtheria or strengthens the resistance of the organism. We look upon mercury as a specific in syphilis, and yet such an eminent authority as Sir Morell Mackenzie never used mercury in the earlier stages of that disease, preferring potassium iodide. Before we speak of the specificity of a drug we should have some tangible idea of what we expect it to do.

Dr. Robinson said that he would be glad to learn of some specific for pneumonia. Of the fatal cases that have come under his observation, death is usually due to the heart giving out. If we could find something to keep the heart going until the virulence of the infection has spent itself, the death-rate from this disease would, doubtless, be largely reduced.

Dr. Peabody said that while it was well enough to be sceptical in regard to the value of certain remedies, they should not be condemned until they had received a thorough and systematic test. If a remedy in the hands of good men has given favorable results in hundreds of cases, there is no reason why we should regard it with distrust until the cases have been increased to the thousands, as we did before adopting the hydrotherapeutic treatment of typhoid fever. To-day almost every physician believes in the value of the cold bath in the treatment of typhoid fever. It is not necessary in every case, but it has practically been adopted as a routine method of treatment; and yet, before we were convinced of its value in this country, a hundred thousand cases or more were treated by that method in Europe with a death rate of only 3 or 4 per cent., while the death rate in our hospital practice ranged between 20 and 25 per cent., and in army practice between 40 and 50 per cent.

Dr. Peabody said that while he did not feel particularly hopeful as regards the treatment of pneumonia by any new method or remedy, he had given sodium salicylate in quite a number of cases, and was much impressed by the frequency with which the disease in those cases disappeared by lysis; furthermore, the patients seem to bear the disease better and suffer less than those who were treated in the usual way or were untreated. The speaker said he was distinctly in favor of all efforts made in the direction of finding specifics for the various diseases, whether we get results in a few years or decades.

Dr. Peabody said he did not regard creosote in any sense as a specific for pulmonary tuberculosis. The beneficial effects of the drug are observed even when the dose is so small that it could not possibly exert a germicidal power.

Dr. Robinson said he did not think the "tubbing" treatment of typhoid fever was very popular outside of the hospital. Personally, he has never resorted to it in private practice.

Dr. Andrew H. Smith, in closing the discussion, said that several observers had noted that when sodium salicylate or carbonate of creosote was given in pneumonia, the disease usually terminated by lysis instead of crisis. The speaker said he attributed this to the fact that the drug seems to exert an inhibitory effect upon the pneumococcus, and this tends to stop the process before it reaches the crisis. In reply to Dr. Peabody's remark regarding the value of creosote in tuberculosis, Dr. Smith said that in pneumonia the conditions we have to deal with are entirely different. In pulmonary tuberculosis the tubercle bacilli are imbedded in a mass of tubercle tissue, and it is doubtful if the creosote can come in contact with the germs; furthermore, the tubercle bacilli are very hardy. On the other hand, the pneumococcus is a germ which is easily affected, and in the lung we get a very concentrated action of the drug—more so than anywhere else in the body, on account of the circulatory conditions in the lungs.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 8, 1902:

	Cases.	Deaths.
Measles	966	21
Diphtheria and croup	266	32
Scarlet fever	337	21
Smallpox	60	10
Varicella	104	..
Tuberculosis	267	183
Typhoid fever	27	8
Cerebro-spinal meningitis	..	8

Warts.—Tom Robinson, M.D., discusses warts in the February *Medical Magazine.* He places them under two sections, congenital warts and acquired warts.

Congenital warts occur, as a rule, singly, and show a marked proclivity for the face and posterior aspect of the trunk. At birth they are often passed unnoticed, until they become darker in color, firmer in structure, and covered with coarse hairs—it is then they become sources of disfigurement and annoyance.

Acquired warts embrace all warts which make their appearance after birth. These, again, must be divided into two groups, the persistent and the fugitive. The warts which come to stay appear usually as rounded elevations of the skin, varying in size from a pin's point to a split pea. They seldom attain a much larger size. They are met with in every region of the body: they vary in color and are modified by position.

With regard to the treatment of warts, Dr. Robinson says: If a crop of warts occur suddenly on either the face or hands, we may rest assured that they will disappear in a few months, in spite of any treatment we may adopt. "All remedies act best where there is a spontaneous tendency towards recovery." Those which are caused by a recognizable irritant will disappear when the irritant is removed. Those which are coeval with birth will be cured only by destruction. We have all of us our favorite escharotic. The one I use in my own practice is a saturated solution of potassæ fusee. This can be applied to the wart by means of a piece of wood. The surrounding skin must be protected by some grease during the operation. It will cause a sharp pain and a sense of throbbing and aching. The effect at first is to produce a copious exudation of viscous amber-colored fluid, as dense as the white of an egg, combined with a black-looking jelly mass, consisting of blood. This should be allowed to dry on the surface, and form a crust; in the course of ten or fourteen days the crust will be hard and fall off.

Examples of Excessive Feeding.—Interesting illustrations of the policy of excessive feeding may be taken from [illegible]. It is well known that many caterpillars gorge enormously. Their growth at this period of life is very rapid, and so also is the development of their structure. But they do not use up a twentieth of what they eat. They defecate continually, and to an enormous amount. Apparently their absorbent organs select what is wanted and disregard the rest, which is the bulk of what they have eaten. It is said that when a herd of nun caterpillars is feeding on the leaves of the spruce fir the noise of their excrement falling on the foliage is like that of a shower of rain. That the feces are not merely débris ejected without change is shown by the fact that they are excellent manure, whereas the spruce leaves themselves are useless. So efficacious is this manure that it is recorded respecting a year in which in Bavaria this caterpillar abounded that the grasses grew most abundantly the following summer. It was further remarked, as a secondary result, that the antlers of the wild deer in the forest were larger than they had ever been before noticed. In regions where locusts abound it is observed, as a set-off to their injurious depredations, that their very abundant excrement serves as an excellent manure. In this instance it is the mature insect which gorges itself, but it is still making growth.—*The Hospital.*

The Electrical Treatment of Phthisis.—Lagriffoul and Denoyès (*Archives d'Électricité Médicale*) have shown that, in the case of tuberculous lesions experimentally induced in the guinea-pig, the action of high frequency currents is to retard or greatly mitigate the development of the disease. In the untreated animals, which were used as a control, the lesions revealed post mortem were much more extensive and more advanced than in those treated electrically. The treatment was effected both by autoconduction and the "effluve," and of the two they found more benefit to follow the effluve moderately applied. Chisholm Williams (*British Medical Journal*), in a paper on the treatment of phthisis by currents of high frequency and high potential, gives the results of the method as applied to forty-three severe cases of pulmonary tuberculosis in the human subject. Of these forty-three patients, forty-two put on weight and lost all symptoms, except in some few a slight cough. The average duration of the treatment was three months, and the sittings were from ten minutes *per diem* upwards.—*Quarterly Medical Journal.*

Arsenical Poisoning, and Cutaneous Pigmentation.—J. C. Muir, Manchester, England, has recently made investigations on this subject and came to the following conclusions: (1) That the blood of arsenical patients having deep cutaneous pigmentation, is decidedly richer in red cells and hæmoglobin than that of similar slightly pigmented or unpigmented cases. (2) That this disproves the almost universally accepted hypothesis that the pigmentation is due to destruction of hæmoglobin or red cells, and is evidence for thinking that the melanin of the skin is an important element in the production of hæmoglobin. (3) That in human beings arsenic causes a decided erythroblastic reaction in the marrow of the long bones, that a slighter but distinct leucoblastic reaction also occurs, which may be in part, or even wholly, due to accompanying tuberculosis. (4) That the erythroblastic function of the marrow is more easily stimulated in the presence of a large store of cutaneous melanin.

Overcrowding and Intemperance.—Dr. F. H. Morison, Medical Officer of Health for West Hartlepool, states that overcrowding in that borough is largely due to the taking in of lodgers into private houses. He believes that unsanitary and overcrowded dwellings are largely a cause, as well as the result, of intemperance. "Can it be expected that a man who sleeps in a room with small cubic space, badly ventilated or not ventilated at all, and with three or four more occupants, will rise in the morning refreshed and able for his day's work? Dr. Morison says it is absolutely impossible. The result is that he feels tired and fagged out, and too early resorts to visit the first public house he comes to on his way to work in the vain hope that spirits may stimulate him sufficiently to carry on his day's work. This I state without fear of contradiction is a fruitful source of drunkenness."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended March 8, 1902:

SMALLPOX—UNITED STATES.

		Cases.	Deaths.

ARE VESSELS INFECTED WITH YELLOW FEVER? SOME PERSONAL OBSERVATIONS.

By HENRY R. CARTER, M.D.,
SURGEON, UNITED STATES MARINE-HOSPITAL SERVICE.

In a paper read before the American Public Health Association at Buffalo, September 18, 1901, Dr. Doty, the Quarantine Officer of New York, affirms the absence of secondary cases of yellow fever aboard vessels; *i. e.* that while cases of this disease contracted ashore develop aboard vessels, yet none are contracted aboard the vessel itself. That is, the vessel does not become "infected" with yellow fever.

The experience of other quarantine officers has been different, and it may be of service, then, to group some cases already of record in which the contrary was observed. It is not proposed to collate a number of examples of vessels, aboard which yellow fever was contracted, from the literature of the subject, but to give very briefly the history of some such vessels personally observed by the writer, from his own notes, during a four-years' service (1888 to 1891 inclusive) at the Quarantine of the Gulf, Chandeleur and Ship Islands. Here were received all vessels believed to be infected with yellow fever bound for all of the Gulf ports, except for New Orleans and from Tampa south. Consequently our clientele was considerable. The bulk of them, however, although certainly the worst class of vessels which entered the Gulf of Mexico, were not, in my opinion, "infected" when I received them; *i. e.* yellow fever could not then have been contracted aboard them.

I will premise here that I accept without reservation the conveyance of yellow fever by an infected mosquito of a certain kind, and that to me a vessel "infected" with yellow fever is simply one which is harboring these infected mosquitos. Whether they come aboard already infected, or, being aboard, became infected by feeding on cases of yellow fever developing aboard ship but contracted ashore, can in general be determined from the history of the spread of the infection. Indeed, it was primarily the history of these and other ships which led to the (tentative) formulating of the laws of the "Interval between the Infecting and Secondary" cases of yellow fever and the "Period of Extrinsic Incubation of Places" of that disease, which, and much else, are so clearly explained by the conveyance by a mosquito host.

The deductions as to the disease being contracted aboard the vessels, when such deduction is made, are, however, independent of the assumption of any theory of conveyance. I do assume, however, that the period of incubation of yellow fever rarely, if ever, exceeds six or six and one-half days.

I.—1888: Ship Island—"Norwegian bark *Magnolia*, 946 tons, fifty-six days from Rio, via Pensacola bar; rock ballast. Left Rio May 20; left two men sick in hospital and had one aboard, considered yellow fever; master sick third day out, May 22; died May 27; all well till June 1, then several (three) got sick at once; first mate sick June 11; died 17, black vomit; all were sick on the way up except two; twenty-one on crew list, including the two men left in Rio. One of these who escaped fever has had yellow fever, and the other is a lad from Dantzig on his first deep-sea voyage. In all, seventeen men were sick of fever *en route*, of whom five died. The last case, Elias Eliasen, developed June 14."

Here, save the captain, all sickened not less than eleven days after leaving Rio, and the first mate and Eliasen on the twenty-third and twenty-sixth day respectively. They then contracted yellow fever aboard ship.

The picture is that of an infection introduced aboard the vessel by the men who sickened in Rio; *i. e.* there were uninfected stegomyiæ aboard, which were infected from these cases and conveyed yellow fever to the remainder of the crew, except the captain, who contracted it ashore. I did not record the dates of the cases of the men left at Rio; it was shortly before clearing. The interval between an infecting and a secondary case is almost always fourteen days or over.

II.—"Italian bark *Riagino*, Rio for Pensacola, fifty-one days out; rock ballast, 560 tons. No sickness in Rio until just before leaving, then sent two men to hospital; left five days after; log shows men were taken June 4 and 6 and removed on the 6th; sailed on June 10; no one had been ashore save master and steward, using a harbor boat. First case reported sick *en route* June 21, one next day; six sick *en route*; three deaths June 28, June 29, and July 14, all with black vomit; crew refused duty at second death; last case well July 13; sixteen on crew list, two in Rio; master has had yellow fever; steward sick just after leaving, not considered yellow fever."

Six cases developed ten days after leaving Rio. Same remarks as were made of the *Magnolia* apply here. No record is made of where these two vessels lay in Rio, the writer not then appreciating the importance of this.

1889.—My notes for 1889 are lost, and, indeed, there may have been in 1888 more than the two vessels given above which should have been included in this paper; but my notes, taken at first solely with the view of determining the period of incubation of yellow fever, give data on only these two sufficiently definite to determine that they were infected; *i. e.* that yellow fever was contracted aboard.

III.—1890.—"British ship *Avon*, in rock ballast; twenty-two in crew, four immune to yellow fever. Sailed from Rio April 20; all well in port and *en route* until thirty-eight days out, when a boy in port watch sickened with yellow fever; taken to hospital, Gulf Quarantine on third day, and died on sixth; another case developed two weeks later, in a quarantine attendant who helped me clean up the room, [illegible] at which the [illegible] was sick aboard the ship.

It is remarkable that there should have been only one case of yellow fever among the crew aboard the vessel. At the time it was ascribed to the fact that the boy, the only one on the port watch, helped a man, shipped in Rio and immune to yellow fever, overhaul his chest a few days before the boy was taken sick. Whether there was an infected mosquito in the chest which had survived that length of time, or whether there was any relation between the chest and the fever, may be a question. It in no way affects the present question that the disease was contracted aboard. It was the first case seen at this station that year.

IV.—"British ship *Cadmus* from Rio Janeiro with rock ballast. No sickness was reported *en route*, in port, or on arrival. She was cleaned July 22 to July 23, 1899, and disinfection completed July 25, in the afternoon; one case of yellow fever developed July 27, the sixty-fourth day out, in the early morning, before day."

V.—"British ship *Chippewa* from Rio Janeiro with rock ballast; no sickness was reported in port, *en route*, or on arrival; she was cleaned July 26 and July 27, and disinfection completed July 28; one man, the quartermaster, developed yellow fever July 29, at night, sixty-eight days out from Rio."

The *Alert* made no port after leaving Rio and communicated with no vessel *en route*. The other two made no port save Pensacola bar, and communicated with no vessel save the pilot boats there and off Mobile bar. The infection in these three vessels, then, must have been contracted aboard. They lay in open roadstead at my station, one and a half miles off shore, and about one half-mile apart, and there was no visiting between them, and none of their crews were ashore.

VI.—"Spanish bark *Castilla*, fifteen days from Cienfuegos via Round Island Quarantine, in rock and earth ballast; fourteen in crew, eight days out from Cienfuegos to Round Island; all well in port, *en route*, and on arrival; mate sickened fourth day after arrival at Round Island while discharging ballast. Vessel sent here in tow August 22, mate has yellow fever, died on the sixth day of illness, captain developed yellow fever day after mate's death, taken to hospital, no other cases of sickness aboard, the remainder of the crew are, save one, Manila men, and all probably immune to yellow fever, being mainly residents of Cuba for many years."

Here two men developed yellow fever, one twelve and one seventeen days after leaving Cienfuegos. The infecting mosquitoes may well have been harbored in the hold, which the mate would probably not have visited until he anchored at Round Island and began discharging ballast, and in which the master would not be apt to go while the mate was on duty.

VII.—"Spanish bark *Gran Canaria*, seven days out from Havana to July 7, all well in port, *en route*, on arrival, and while in quarantine, crew probably all immune to yellow fever, being mainly Manila men and old residents of Havana. O. F., quarantine employee, went aboard as ballast master, next day developed yellow fever July 11. This man had been exposed to no possible source of infection for the six months previous, except this vessel."

A case nearly similar to the above occurred in 1880, but I have no notes of it.

VIII.—"Norwegian bark *Queen of the South*, in rock ballast, Rio for Pensacola, fifty-four days out, left Rio with seventeen men, six deaths *en route*; all well in Rio. Lay at Mocanque, a healthful part of the harbor, no shore leave allowed ashore, but he went in ship's boat, left one man in convalescence, shipped one man, a negro, in his place; sailed April 23, master sick April 26, second mate sick night of May 10, two men May 11, one man May 12, two men morning of 13th, two during day of 13th, one man sick and one died 15th, one man died 15th, two sick 17th, one died 19th, two died 21st and 22d, one sick 21st, one died 25th; thirteen sick *en route*, five died. The man shipped in Rio [illegible] and one of the others immune by previous attack."

The picture is very clear of a clean ship infected by the illness of the master contracted ashore; he had *uninfected* mosquitoes aboard, which became infected from the master sick of yellow fever, and conveyed it to the crew.

IX.—1891.—"British ship *Curlew*, fifty-seven days from Rio for Pensacola. Lay in the Gamboa last eight days. Two sick men February 27; taken to hospital that day; sailed March 1; master sick March 1; five men besides him that night; two men March 4, one March 5, and two more during the day; two men sick March 7; two men died the 19th, sickening the 13th and 15th respectively, both with black vomit; all aboard here, nineteen, were sick *en route* except one, a Barbadoes negro, but don't believe all had yellow fever, the crew having been badly frightened. The earlier cases and the three who died were undoubtedly yellow fever, as were the steward and mate."

Here we have two cases, at least, developing thirteen and fifteen days after leaving Rio.

X.—"Swedish ship *Condoren*, seventy-nine days out from Rio via Pernambuco for Mobile. Rock and earth ballast. Eighteen in crew, all well in port, lay in Gamboa last five days; no shore leave allowed, but took ship's boat to go ashore; sailed March 3; three men sick March 5, sixteen men sick all told up to March 26, and six deaths. Last man got sick March 26, when she put into Pernambuco short-handed and sent three sick to hospital. Two men sick March 20, four men sick March 18; one man sick March 26 (really night of 25th). At Pernambuco she lay eleven days and was disinfected by sulphur. Shipped eight new men, four, probably five, of them immune to yellow fever. Developed no sickness on the rest of the way up."

Here four men developed yellow fever fifteen days from Rio.

XI.—"German ship *Gustav and Oscar*, Rio for Pensacola. Lay at Cobras, a healthful place. One case yellow fever at Rio, March 22, sent to hospital March 24; no shore leave allowed, sailed from Rio April 1, first case, sickened April 7, two men, three next day, one next morning, and two during the day of the 9th; one death on 10th, leaving six men sick, captain sick on the tenth at night after supper, last case on 14th; two deaths on the 11th; one on the 12th; crew list shows twenty-one men left Rio; fourteen sick and four deaths *en route*. It is reasonably certain that four of the remaining crew were immune to yellow fever by previous attack."

XII.—"Norwegian bark *Crown Prince*, fifty-eight days out from Rio for Ship Island. Lay at Mocanque, no sickness aboard in Rio, no shore leave granted and did not use ship's boat to go ashore, sailed April 29th, master sick second day out (April 30), next case May 16; three (two after and one forward) became sick, May 17, two sick in morning, one in the day, May 18, three men in forecastle sick, May 20, two sick, one death; May 21, one death, one sick; May 23, two deaths; May

24, one sick; May 28, one death last night; May 29, one sick this morning; May 30, one death." The one case on the 29th was the last case taken sick. There were fourteen men aboard and every man had fever, six dying. She put into Barbadoes on June 10, disinfected, and shipped (in quarantine) four new men, one probably unacclimated. No more sickness *en route*."

All of these cases, except the captain's, were not less than sixteen days from Rio before developing.

XIII.—"French ship *Emily Postel*, twelve days from Vera Cruz via Pensacola Quarantine. Had "sickness" aboard just before leaving Vera Cruz, one man; sailed from Vera Cruz July 28; no sickness since until the crew went to discharge ballast, August 12; one man sick yellow fever August 15; two men the same August 19, and one man August 20; disinfection by sulphur was done on the appearance of the first case of yellow fever, and no case occurred save the above."

All were developed more than sixteen days after leaving Vera Cruz, hence from infection on board. The history points to infection (infected mosquitos) in the hold.

The picture given by the *Curlew* and *Condoren* are those of disease conveyed by mosquitos coming aboard *already* infected just before they sailed. The infection was not introduced by the men who first sickened. The interval between them and the next cases was too short. Observe that they lay in the Gamboa, directly in the lee of a town badly infected. The other two give the usual history of a clean place (town or vessel) infected by some one *developing* yellow fever, contracted elsewhere, in it.

XIV.—Dr. G. (Assistant Surgeon, U. S. M. H. S.) developed yellow fever June 18 at the Gulf Quarantine station, and died June 29. He was immediately from New York, where he had been on duty for some months, and had been at the station but fourteen days when he was taken ill. There had been no case of yellow fever at the station that year. There were a number of vessels in quarantine, but the *Gustav and Oscar* (No. XI.) was the only one I judged to be infected. On this vessel, as on the others, he had been with me inspecting, opening up drawers and boxes, and going into every compartment, etc., for the disinfection. I thought his infection was from this vessel. It was certainly from *some* vessel.

I think it will be granted from the above that the ability of a vessel to carry the infection of yellow fever is no myth. Here are thirteen vessels which did so carry it collated from only three years' observation at a single station. Such vessels are, indeed, rarer, much rarer, now than they were before 1894, yet they still come. I saw two at Tortugas in 1894. Other cases are reported by Geddings and by Echemendia at the same place and at Port Tampa Quarantine. Rosenau reports a case contracted aboard the steamship *Vigilancia* from New York, plying between New York and Vera Cruz, via Havana, in 1899. The steamship *Bodo* last year (1900), from Bocas del Toro for Mobile, developed three cases of yellow fever, seven, eight and nine days out from Bocas. It would not be difficult, I think, to multiply instances of recent date, yet that they are rarer is without question. On the factors which have brought this about we can barely touch.

Obviously there are two methods by which vessels can become infected: (*a*) A case of yellow fever contracted elsewhere may develop aboard a vessel already harboring stegomyia mosquitos which become contaminated from it; (*b*) The stegomyia mosquitos may come aboard already contaminated. In the first case, there being nearly always over two weeks between the infecting and the first secondary cases of yellow fever, it results that, if the first case occurs after leaving port, vessels, even sailing vessels, from Cuba and the Caribbean Sea, will generally reach quarantine and (if at a southern station) be disinfected; *i. e.* mosquitos killed, before it is time for the secondary cases to develop or, indeed, to be contracted. This agrees with all observation. In vessels infected in the second way, cases of yellow fever may occur after a very short time, or no interval, from leaving port. The causes then which have lessened the number of infected vessels at United States ports are:

(1) The very great falling off of vessels from Rio and Santos since the establishment of the Brazilian republic. This does away with the bulk of the "long-trip vessels" we used to have, which are the only ones developing secondary cases *en route* if infected by a case of yellow fever developing aboard (*vide a*).

(2) The replacing of sailing craft by steamships. That steamers convey yellow fever less frequently than sailing vessels has long been known. This is because they lie a much less time in an infected port, and the discipline of their crews is better; no shore leave means no man goes ashore. They also make quicker trips, and thus are not apt to develop secondary cases *en route*, even if yellow fever contracted elsewhere develops aboard and they have the stegomyia aboard. It is also to be noted that the worst parts of the harbors of Havana and Rio, above San José wharf and the Gamboa, have never been berths for steamships. Note, too, that the sailing vessels displaced are the foreign sailing vessels; the American schooner was less often infected than foreign vessels.

(3) Especially since 1893, and to some extent before, supervision has been kept by United States Sanitary Inspectors in the more dangerous yellow-fever ports over vessels bound for the United States, especially of passenger vessels. Certain anchorages have been recommended as safe, others have been forbidden, notably the Gamboa at Rio and certain wharves and parts of the harbor of Havana. Passengers who it is believed will develop infection aboard have been barred; shipment of new men in the infected port carefully supervised; vessels in which yellow fever has occurred in port are disinfected before leaving, and many other measures taken to have the vessel to leave port clean, or as nearly clean as commercial considerations allow. In general, the vessel owners, especially of the regular lines, have given hearty cooperation in these measures, as well as in keeping the crew aboard, and in confining to daylight the visits of such officers as must go ashore. These restrictions, especially the last, have by no means been absolute for all classes of vessels, but are well observed, in Cuban and Mexican ports at least, by probably over five-sixths of the tonnage. The sanitary measures to avoid infection (3) and the proportionate substitution of foreign sailing vessels by steamships (2), are without doubt the main factors acting in cooperation in lessening the infection of ships. No one can read Burgess' list of infected vessels in Havana Harbor (Report, U. S. M. H. S., 1896) without noting how great has been that increase in recent years.

We have said that if a case of yellow fever develops aboard a vessel harboring the stegomyia mosquito (proper conditions of temperature being premised) they may become contaminated by feeding on him and infect others. A vessel which have no stegomyia aboard, or like non-infectible territory, and will not communicate infection even if cases of yellow fever develop aboard. I think it fair to say that vessels plying to and from southern ports of the United States will, during the summer season, generally have the stegomyia aboard independently of its berth in tropical harbors, and may at times breed them in their water supply. This mosquito, however, seems to be rare north of Virginia (though its distribution has not been sufficiently investigated however), and a vessel plying to and from a northern port of the United States would not harbor this mosquito unless it came aboard in the tropical port. Now how far this mosquito goes, or is borne from shore, has not, I think, been directly investigated, but we do know that the crews of vessels moored off from shore (say, two hundred or more fathoms) in that part of Havana harbor seaward from the line between the Station Catalina warehouses and the Machina wharf do not develop yellow fever (unless close to some vessel which is infected). This means that *contaminated* stegomyia, at least, do not go so far from shore. Lying then at the anchorages accounted safe in Havana harbor, where the passenger vessels for the United States lie, one would think that the probability of any stegomyia coming aboard would be small. At Vera Cruz the vessels must lie nearer ashore (although to windward of it), and experience shows that the crews of vessels lying there are not entirely safe—as I believe them to be in Havana—although infection in the part of the harbor picked out as safe is decidedly rare. The anchorages in both harbors regarded as safe are well to the windward of the town all summer. A direct investigation of this matter, *i. e.* the presence of the stegomyia aboard vessels from northern ports in different parts of the harbor of Havana and other tropical harbors should be made. To sum up:

1. Vessels aboard which yellow fever had been contracted, *i. e.* vessels infected with yellow fever, have not been rare, at least at southern quarantine stations.

2. Such vessels are much rarer since 1893, and are not very common now.

3. That the diminution of the number of infected vessels reaching United States ports is due mainly to the sanitary measures for avoiding exposure to infection in the foreign port, and to the substitution of steam for sailing vessels. To some degree the falling off of the vessels from Brazilian ports is also a factor.

4. That a case of yellow fever developing aboard a vessel plying between southern ports of the United States and the tropics will probably infect the vessel, so that other cases can, if time be given, be contracted aboard her.

5. Such vessels, however, if short-trip vessels, not more than ten or twelve days *en route* after the occurrence of the case of yellow fever, will in general be disinfected at southern quarantine stations before any other cases have been contracted aboard, although harboring infected mosquitos.

6. That a case of yellow fever so occurring aboard a vessel from a northern part of the United States would be able to infect her or not according to whether she had acquired the mosquitos stegomyia fas. in the tropical port.

7. It is, in general, then, necessary to disinfect all vessels running between southern ports of the United States and tropical ports if a case of yellow fever occurs aboard, no matter where it be contracted; while vessels running between northern ports and the tropics may, through precautions in tropical harbors, have no stegomyia aboard, and are thus not infectible by cases of yellow fever occurring aboard.

8. Some vessels giving no history of yellow fever in port, *en route*, or on arrival—even when many days *en route*—are nevertheless infected, and communicate the yellow fever to those who go aboard (*vide* Nos. IV, V, VI, VII). Note also the first case aboard the *Amor*, No. III, was thirty-eight days out from Rio. This is probably due to the infection (infected mosquitos) in parts of the vessels unfrequented by the crew while *en route*, or to the crew being all immune to yellow fever.

PATHOLOGY OF APPENDICITIS

WITH SPECIAL REFERENCE TO FOREIGN BODIES IN THE APPENDIX

NEW SURGICAL POINTS

By J. COPLIN STINSON, M.D., [illegible]
SAN FRANCISCO, CAL.

The appendix consists of the same structures that belong to the cæcum, except that there is an excess of lymphoid tissue. The connective-tissue layers, the most important of which is located between the lymphoid tissue and the longitudinal muscle, become, in appendicitis, greatly distended with serum, and thus form a strong factor in strangulation of the other layers.

The principal arterial supply of the appendix is from a branch of the ileocolic artery, which passes along the free margin of the mesappendix, and its arrangement is of some clinical importance. In some women the appendix receives a little collateral circulation by way of the appendiculo-ovarian ligament.

The lymphatics of the appendix pass largely to a ganglion at the cæcal extremity.

The lymphoid or submucous coat and the serosa of the appendix are connected through gaps in the muscular layers, and through these gaps an infection can quickly spread to the investing peritoneum or, conversely, to the mucous coat. The nerves of the appendix are from the superior mesenteric plexus of the sympathetic system, which is widely distributed to the small intestine, and this explains why patients often suffer from colic and general abdominal pain or pain at the navel, without realizing that its origin is at the appendix a little part of the whole. Thus, it is nearly the exception for the pain to be located in the appendix at the outset of an inflammatory attack.

The contents of the appendix usually consist of mucus and some fecal matter, and under normal conditions fecal matter and gas find easy entrance to and exit from an appendix on account of contractions of its muscular layers. A very little swelling of the inner or other coats suffices to obstruct the lumen. Thus a concretion or foreign body which is about the size of the lumen of the appendix readily enters, comes closely in contact with the mucous coat and, in consequence of contractions of the muscular layers, sets up irritation in the mucus and other layers, with resulting congestion and subsequent inflammation, ulceration, etc., unless it is expelled.

Concretions are of three kinds: fecal, phosphatic, and fatty, and are formed in the cæcum, appendix, or elsewhere by a bit of fecal matter being rolled into a ball or rod, and cemented with mucus; insoluble salts being precipitated from the fermenting mucus, and arranging themselves more or less in layers, alternately with the other elements of the altered mucus. Phosphatic concretions are also formed as a result of decomposition of mucus. Phosphate of calcium is the common, and sometimes the only ingredient of a concretion which may become as large as a hickory nut.

The large proportion of fat in some concretions is in all probability due to fatty degeneration of the lymphoid cells of the appendix.

Concretions are round, flat, oval, or rod-shaped, some occur singly, others multiple. Various kinds of seeds are closely simulated by concretions, and this accounts for the popular error that seeds are apt to get caught in the appendix.

Fatty concretions probably occur only as a result of long ulceration of the lymphoid coat.

Bacteria are also found in the appendix. The colon bacilli which are found normally in the colon are almost invariably present in the lumen of the appendix, and they are harmless dwellers there unless an irritation, as already mentioned, gives them an opportunity to migrate into the tissues. Streptococci are also quite constantly found. Many of the less important pyogenic bacteria and saprophytes or bacteria fermentation lurk in the appendix, awaiting the advent of conditions which will be favorable for their rapid multiplication. When an irritation is produced and inflammation sets in, the growth is usually mixed in character. The streptococci are at first more energetic than the others, but later the colon bacilli predominate. Sometimes entoza are found in the appendix.

According to my observations, appendicitis is an inflammation of the appendix vermiformis, originating in any cause that produces an irritation within or without the tissues of the appendix, the irritation causing congestion of the adjacent layer or layers, and later inflammation occurs in consequence of bacterial invasion, the organisms swarming into the adjacent layer or layers and depositing inflammatory products within them, stasis and exudation being much favored by the compression of the muscular, connective tissue and peritoneal layers of the appendix. Thus the principal cause of appendicitis is some local irritant, *i. e.* a concretion, entozoa, or foreign body that locates itself within the appendix and injures its mucous coat. The chief cause for bacterial infection within the appendix is the trauma to the mucosa. Sometimes the appendix is injured by accidental twists, violence from without and adjacent violent muscular contractions. An infection occurs at times in its peritoneal coat by extension of a local or general peritonitis to the appendix.

As the result of a lesion in the mucosa, microorganisms swarm into the tissues through the break, the bacteria multiply, toxins form as the result of bacterial growth, and in consequence of the invasion, serum is exuded into the tissues of the appendix, placing such tissues under the influence of serum compression. The lymphoid coat of the appendix and its connective-tissue layer, forming the principal part of the inner tube of the appendix, swells as a result of congestion of its layers, and the contractions of the muscular layers of the appendix stimulates the branches of Auerbach's plexus. This extends to other parts of the intestines, causing irregular spasm, producing colics, and thus over-stimulation of the sympathetic system extends still farther, and the vaso-motors cause the heart to contract rapidly, producing rapid pulse.

The layers of the appendix, on account of its indistensibility, through the rigidity of the serosa and connective tissue layers, undergo rapid destructive changes, its cells readily succumbing to the toxic destruction of bacteria. The infected appendix with its lymphatic and blood circulation obstructed, is not reached by a collateral circulation which can bring leucocytes to act as protectors, and consequently the bacteria are free to destroy. Sometimes when the lesion is not progressive, nature gets the upper hand, and we note the processes to the normal state, resolution taking place here the same as a resolving inflammation in other localities, thus leucocytes are carried freely to the place of infection, the bacteria, etc., are overcome and recovery sets in. The appendix, however, in most instances, is particularly unfitted to receive help, for when its single-artery circulation is blocked, the appendix stands out as an isolated area of infection, cut off from protection, and bacteria are at liberty to continue their work. A sufficient degree of exudation compression having cut off the access of leucocytes, the toxin destruction of the inner tube of the appendix progresses. In milder cases, as in appendicular colic, there is simply desquamation of patches of mucosa, but the injury is not easily repaired, and the bacteria lurking in such a disabled appendix may keep up a certain degree of malign influence, sometimes for many years, though the patient be unaware of the fact. Bacteria in the lumen of the appendix are ready to make new attacks at any favorable moment, so that the appendix when once crippled may be readily infected in the future, because when once an irritation has been produced within its lumen, and has acted upon its walls, pathological changes have been produced by inflammation, its complications and sequelæ, *i. e.* ulceration, scar formation, strictures of the lumen, etc., which predispose to future infections.

There is no specific microbe for appendicitis. The colon bacillus is always present, and there is a very decided tendency on the part of the streptococci and colon bacilli to outstrip the others, and finally the colon bacilli usually gains the mastery.

The temperature in appendicitis does not indicate the extent of infection, but gives a clue to the character of the infection. Thus, high temperatures more often occur when the infection is mixed, or caused by streptococci. A temperature of 103° F., or more, at the outset of an attack of appendicitis seems to mean that the toxins of mixed bacteria are sending the temperature up. The temperature in early appendicitis is not often elevated: a colon bacillus infection may show a normal or subnormal temperature from the outset, and such a temperature may continue while the most disastrous effects are being produced by the bactera in the tissues.

R. T. Morris has noted abscess of the liver in some of these cases as early as on the fifth day. There is no doubt that hepatic abscesses appear in some cases of appendicitis that are too mild to attract the attention of the physician directly to their original cause. The solitary artery of the appendix is obstructed sometimes in accidental twists of the appendix.

Dyspeptic symptoms are usually the result of fresh or old adhesions, and they are complications that can usually be cured by operation.

Peritonitis is the most important complication of appendicitis. The least severe form is limited to the peritoneum of the appendix and mesappendix. The irritating products of bacteria at work within cause a reddening and roughening of the serosa. The mesappendix contracts firmly, and remains fixed by adhesions if the inflammatory process is severe enough to produce plastic exudate. When the peritonitis spreads beyond the appendix the exudate covers adjacent peritoneum and thus more or less surrounds the appendix.

This is Nature's method of walling off the inflammation, and, unless bacteria have gained the headway, the inflammation is encapsulated. When the inflammation is more intense, either no plastic exudate forms, or what does form is liquefied, and the progress being more or less rapid, diffuse peritonitis occurs. The peritoneum does great service for or against the present, according to the [illegible] of the physician or surgeon in charge. The extent of peritonitis following from appendicitis bears no direct relation to the extent of destruction in the appendix itself. Most violent peritonitis can occur in cases in which bacteria have migrated from the appendix via the lymphatics, connective or loose connective tissue, and not through a perforation in the walls of the appendix. On the other hand, a little local peritonitis may suffice to wall in a perforated or completely sloughing appendix. The relative importance of peritonitis depends upon whether the rupture occurs intra- or extraperitoneally. If intraperitoneally, the inflammation will surely be rapidly diffused if not walled off by omentum or plastic exudate; if extraperitoneal, the inflammation will usually be local, with the formation of one or more abscesses. The appendix is very seldom totally destroyed by one or more attacks of inflammation, unless the attack happens to be fatal. In those cases wherein one or more abscesses form, the appendix is usually but slightly destroyed. Thus the appendix should always be removed at the primary operation, no matter what stage of the disease, if the patient's condition permits; otherwise remove it later on.

When protective lymph is thrown out and, subsequently, bacteria have liquefied it, the peritoneum in many cases keeps on trying to protect by putting up new plastic walls further and further away, thus a large walled-in abscess frequently results. Very often the plastic exudate becomes liquefied in several places by bacteria leaving firm exudate in the intervals and thus multiple abscesses are produced. We must separate all adhesions in operating upon acute cases with pus to be sure that all abscesses are discovered and opened, for a very small abscess, if overlooked, can prove fatal. An abscess sometimes fails to evacuate itself, and, not proving fatal, may remain encapsulated for a long time, render the patient an invalid, and, in addition, subjects him to the distress of acute exacerbations of inflammation. An abscess, whether formed intra- or extraperitoneally, if neglected by the physician or surgeon in charge, may rupture externally through the skin, internally into the intestine, peritoneal cavity, or perforate the ureter, bladder, iliac vessels, or even the pleura and lung.

Thus appendicitis with abscess is, consequently, a most critical condition. A large abscess may form with comparatively little pain, or a small one with much pain on account of pressure on nerves or unyielding tissues. Adhesion bands are extremely common after appendicitis. The plastic exudate when recent and small in amount may undergo complete absorption in some cases; in others adhesions remain permanently, yet cause but little trouble. In some others the adhesions are pulled out into long bands by the moving viscera or omentum becoming adherent, and being moved around, become rolled up like a rope, or divide into filaments, which trap loops of intestine. Adhesion bands thus cause volvulus and kinking of the bowel, inhibit peristalsis of the colon, and produce intestinal strangulation even years after an attack of appendicitis. The most frequent complications caused by adhesions are chronic constipation from diminished peristalsis, or occasional attacks of colic from temporary incarceration of knuckles of bowel. Phlebitis of the iliac and femoral veins is a complication that may cause death in a case that might otherwise be a moderate one. Acute suppurative nephritis may appear early in the disease and carry away the patient.

Septic pleurisy and pneumonia may suddenly and unexpectedly develop in any stage of the disease. Tuberculosis and carcinoma of the appendix are sometimes complications. The simple stage of appendicitis causes symptoms when sloughing and ulceration of mucosa causes a small portion of the length of the appendix to disappear by ulceration or by sloughing. Thus when ulceration occurs in such a case, the injury left in the tissues is closed by granulation with resulting indurative tissue formations, which slowly contract and narrow or close the lumen of the appendix. Such a patient may be free from symptoms of appendicitis in two or three days, but the injury has been done. More erosions of the mucosa and lymphoid tissue will in all probability follow on account of constriction of the lumen. Connective tissue gradually replaces the broken-down inner tube, and if it is evenly replaced without the formation of a stricture the disease may eventually disappear. In these chronic cases the structures, excepting the mucosa, frequently become hypertrophied during the infection, but finally sometimes nothing remains except a string of connective tissue, surrounded by ill-defined portions of mucosa, muscle, and peritoneum. We cannot reasonably expect that the disease will terminate in this way because more infection frequently brings the case to an abrupt termination. In the active cases all the layers are rapidly destroyed. Females suffer less than males, as they expose themselves less to trauma, their pelves are wider and not so likely to hold a displaced appendix in an abnormal position, and their attacks may not be so severe, as sometimes there is a collateral circulation through the appendiculo-ovarian ligament. Thus about twenty per cent. of the cases are women. Appendicitis is most common in both sexes between the ages of ten and thirty-five, but it may occur in the infant at the breast, or the aged. The very young, and those past middle life, expose themselves less to trauma. It is important to remember that the inflammation may spread along the lympathics to the right broad ligament, so that appendicitis may be mistaken for ovarian inflammation or salpyngitis.

From a clinical standpoint, a nomenclature has been sought for the description of various kinds of appendicitis, but apparently there is only one kind. We may speak of a case as appendicular colic, catarrhal, acute or chronic, perforative or suppurative appendicitis, and so on indefinitely; appendicular colic may be present one day, catarrhal the next day, and perforative appendicitis a couple of days later, and still later, in the same case, gangrene may occur. Thus the various phenomena of appendicitis should not be described as indicating different kinds of appendicitis, but rather as marking different stages of one kind of disease.

The diagnosis of the stage of the disease can only with certainty be made at and after the operation. We do not know when an attack will stop, because the resisting power of the appendix to disease advancement is absolutely unknown. We can sometimes place a case in a certain sort of classification from clinical symptoms, and after we have seen the appendix we have found we have more or less guessed it right, but should we classify cases clinically, as abscess, fulminating, etc., cases, we are doing so from the symptoms of complications without reference to the actual condition of the appendix.

There are no groups of symptoms which will allow us to make a positive prognosis as to the eventual outcome of a case, and we must abandon the hope of having any such classification of symptoms for a guide. Attempts have been made from groups of cases to classify symptoms for prognosis, but they fail, because of the nature of the disease.

There is but one rule to follow, and that is to remove the appendix as soon as the diagnosis is made, no matter what the stage of the disease, as experience has now shown us that such is the safest method of treating appendicitis and preventing complications and sequelæ.

Foreign Bodies in the Appendix.—It is considered that in about 7 per cent. of all cases of appendicitis there were true foreign bodies found. The objects that have been found in the appendix are shots, bullets, pins, worms, gallstones, teeth, pieces of bone, grape seeds, cherry stones, tongue-grass, whisk broom, pieces of fish fin, oat-husks, date seeds, apple pips, and beans. At a post-mortem examination Holmes found 122 bird shot in an appendix, and the patient, a man, had had no symptoms during life which pointed to the appendix. Sharp pointed bodies, as pins or spiculæ of bones, are common and quite dangerous. Coleman recorded a case in which a piece of bone was found in a dilated appendix, and had evidently been present for a long time, but externally there were no signs of inflammation. Thus while foreign bodies generally cause rapidly progressive inflammation, yet even large and rough bodies may give rise to no symptoms at all, or may lead to chronic or recurrent appendicitis. Mitchell collected thirty-three cases in which a pin was found in the appendix at operation or autopsy, two instances in which a pin had perforated the cæcum; and in no single case had there been any knowledge of swallowing a pin. Pins lodge more often in the appendix of males than females. Many are seen in children under ten years of age; others in adults in various occupations and conditions of life. Generally foreign bodies, such as pins or other sharp slender bodies, lead to rapid perforation and abscess formation, etc., but not always, and any type of appendicitis may result, with symptoms lasting for months or years. A pin usually enters the appendix straight by its head or point, with its long axis parallel to that of the appendix, and perforation usually occurs with its point, but exceptionally it lays directly across the lumen and perforates the walls with its point and head. McBurney removed an appendix containing two pins perforating the opposite walls of the appendix. In two cases pins have been found in appendicitis within hernial sacs. A pin or other body may be rusted, corroded, or free from deposit; but usually it is the nucleus of a fecal concretion which covers it, but leaves the sharp portion free. In seven out of twenty-eight cases there was abscess of the liver.

The writer reports, in addition, a case of appendicitis in which he found two foreign bodies—two beans—which produced perforations and multiple abscess formations. Operation was performed with recovery. The patient, A. B., was a man past middle life. In November, 1899, he was troubled with pains and cramps in the abdomen, pain in the right lumbar region, and indigestion, for which he was dieted with relief for a time. On February 14, 1900, while at lunch, he was taken with severe pains in the center of the abdomen. He took blackberry brandy, ginger, etc., which relieved him somewhat. On February 15 the pains returned, and, in addition, severe right lumbar pain, which confined him to bed. The following morning his physician was called and his case was pronounced one of acute gastritis following la grippe. After three weeks he was discharged as cured. Upon recovery he enjoyed good health and gained about ten pounds in weight. Early in November, 1900, he became troubled with bladder symptoms, pains and frequent urinations, for which medicines were taken without success. About this time the patient ate frequently of a Mexican dish containing beans. On February 9, 1901, he was taken ill with severe pains in the abdomen. Hot applications were applied and relieved him for a while. On February 11 his physician was called, who, after examining him, pronounced him ill with appendicitis, and ordered applications of hot flaxseed poultices.

He had pain all over the abdomen for three days, more severe on the left side. On the 13th he began to have pains in the right side, which later became more severe on the right side than on the left, bowels constipated and some vomiting. On this date a consultation was held and operation was advised. The patient would not submit and the poultices were continued. His temperature during this time ranged from 99° to 102°.

I saw the patient with Drs. Mark Neumann and Bell, February 23. We made an examination under anæsthesia, and at the patient's home, on February 25, I performed operation, assisted by Dr. Mark Neumann. Ether and chloroform were administered in separate bottles by the drop method; in the main ether being given.

An incision an inch long was made two inches from the spine and about parallel with Ponpart's ligament. The structures of the abdominal wall were divided in the direction of their fibers and the peritoneum opened. After exploration, I found it necessary to enlarge the incision slightly, and it now measured one and three-quarter inches. The upper end of the incision extended about a half inch above a line drawn from the anterior spine to the navel.

I progressed mostly by the sense of touch, using blunt dissection with the index finger, and worked along the iliac fossa, between it and the cæcum, separating adhesions until I came upon an abscess, which was freely opened and flushed out with hot water. From this abscess cavity the two beans were removed, the larger measured thirteen-sixteenths of an inch long and half an inch wide; the other nine-sixteenths of an inch long, five-sixteenths of an inch wide. The beans were carefully examined by every one present, split open and found to be perfect; their capsules being intact, and apparently not affected by either the passage along the digestive track, their stay in the appendix, or the abscess cavity.

Through a common opening, the abscess passing up towards the kidneys and the one down in the pelvis were opened and washed out. Adhesions were freed on all sides. The appendix was separated by blunt dissection from adhesions and its mesentery.

A large mass of inflamed, thickened omentum, covered with pus, was brought to the surface. The pus was sponged and washed away. The appendix was inflamed, suppurating, partly gangrenous, and perforated in two places; the cæcum was also inflamed and sloughy. All intestines in sight were inflamed. All inflamed omentum was removed, the excision being performed well in normal tissues; no mass ligatures were used, the vessels only being ligated with fine catgut, and then the omentum was cut off external to the tied vessels.

During the removal of the appendix it was so soft and friable that it tore completely across, and it was consequently removed in pieces. It was excised close up the cæcum by blunt dissection. The cæcum was deeply located, and could not be brought to the surface without irreparable damage. I tried to close the opening in the cæcum by inserting several through-and-through, continuous catgut sutures, but most of them did not hold, as the layers forming the cæcal wall were very soft. As the cæcum was deeply located and the stitches did not hold, I used borated gauze packing to bring the edges together and close opening. All pathologic and exposed intestines were freely irrigated with hot water as hot as the hand could bear; all visible pus, shreds, plastic fibrin, exudate, etc., on the surface of the bowels, etc., were removed with the fingers, gauze pads and hot-water eruptions. The infected portions of the abdominal cavity, intestines, etc., were dried and again thoroughly flushed with hot water till the fluid came away clear, dried with sponges, and the intestines returned to the abdomen as near as possible to their normal positions.

The peritonitis was of that character which nature had the opportunity of throwing out considerable protective adhesions.

The inflamed, bloody surface at the stump, the edges of the opening in the cæcum, the adjacent peritoneum, and the abscess cavities were lightly dusted with aristol. A strip of borated gauze two inches wide and a yard long was carried to the bottom of each of the abscess cavities, the surfaces lightly packed, and the ends brought as far as possible in direct lines to the surface through the abdominal incision.

The surface of the cæcum was lightly covered with borated gauze and the balance of the wound also lightly packed with more gauze strips, and borated gauze dressings, cotton, adhesive strips, and binder applied, the patient was put to bed in good condition. The recovery was satisfactory, the intestinal contents were discharged several times through the incision during the first week, but the wound and abdominal wall, including the skin, was solidly and durably healed by the latter part of March, 1901. His general health is good. He feels well and looks well, is working at his occupation every day; appetite and digestion good; bowels fairly regular; abdominal wall solid, there is no evidence of hernia, and he does not wear an abdominal support or truss.

New Surgical Points.—In an article on "Appendicitis," a report of fifty-four consecutive operative cases, when to operate, points in technique, which I published in the *American Medico-Surgical Bulletin*, June 13, 1896, I reviewed the several methods of treatment, and from a study of the cases cited and comparison of the methods used by various physicians and surgeons, I then came to the following conclusions:

"1. That appendicitis is strictly a surgical disease.

"2. That an infected appendix should be removed as soon as the diagnosis is made.

"3. That in many cases of appendicitis an inch-and-a-half incision is sufficient for operative treatment.

"4. That if there is local or general infection, the abscess cavities should be freely washed out with hot saline solution.

"5. That if drainage is necessitated, one or two capillary wicks should be used instead of iodoform or other gauze packing, glass, or other stiff tubes.

"6. That to prevent hernia the incision should be small, and if drainage is necessitated a small wick should be used, and the wound be closed, layer by layer, separately and accurately, with sterilized, chromicized tendon or chromicized catgut sutures."

Of the above fifty-four consecutive operative cases of appendicitis in which I performed or assisted in performing while house surgeon at the New York Post-Graduate Hospital during 1893 and 1894, and since I left that institution, up to April, 1896, there were two deaths. These two fatal cases I assisted in operating upon while I was in the Post-Graduate Hospital. Since April 1896, I have operated upon sixteen additional cases of appendicitis, and so far all my operations for appendicitis have been without mortality.

In the article in the *Bulletin* I also described what I considered the best methods of exercising the appendix. Briefly, these methods are as follows:

The mesentery of the appendix is separated by dissection down to the cæcum, bleeding vessels or vessels being ligated with fine catgut, the appendix is held up by the tip, and after dividing in a circle the peritoneal and muscular coat of the appendix about one-quarter of an inch from the appendicocæcal junction, leaving the peritoneal and muscular coats intact, dissect back to the cæcum with handle of the scalpel the divided serous and muscular coats of the appendix. Next apply a narrow-bladed forceps transversely to the mucous cylinder close to the cæcum to temporarily close the opening at appendicocæcal junction, then cut off the appendix close to the forceps, leaving only a small cuff of mucous membrane projecting beyond the outer edge of the forceps. Cleanse the cuff with a gauze pad wrung out of a 1-2000 bichloride solution, then suture the cut edges of the mucous membrane and lymphoid coats very closely and accurately together with fine silk on a fine needle. Disinfect united edges and line of suture, remove forceps, and suture accurately the peritoneal and muscular coats which have been dissected back to cæcum. If the coats of the appendix are matted together, apply the narrow-bladed forceps transversely to all coats at the appendicocæcal junction. Next, cut off appendix close to forceps, leaving only a small cuff of the divided coats projecting beyond the outer edge of forceps. Disinfect protruding mucous membrane, etc., and suture cut edges closely together with fine silk and fine needle; disinfect line of suture, remove forceps, and bury this line of sutures with a layer of serous sutures.

"The methods above described can be quickly done. In both only sufficient mucous membrane and other coats of the appendix are used to close accurately the opening in the cæcum at the appendicocæcal junction without leaving any tension on the line of sutures, and after suturing is finished there remains simply a line of sutures on cæcal wall at the former location of appendix. If the appendix is gangrenous, and the softening process has extended even to the cæcum, have an assistant pinch up the adjacent portion of cæcum with a dry piece of gauze to prevent extravasation, then remove the appendix and irreparably softened cæcum, and suture the layers accurately together with fine stitches. This line of sutures is then buried with one or more layers of Lembert sutures."

These are the methods I use when sutures can be inserted, with the exception that I use fine chromicized catgut for sutures instead of silk. In those cases wherein sutures do not hold, the edges can be approximated by borated gauze packing, which assists in union. The writer has found this latter method to be followed by satisfactory results.

By performing early operations, and by using short incisions instead of long ones, the mortality has been much lowered; less time is taken for the operation, less injury is done, the wound being small, can be closed in less time and with few manipulations; healing takes place rapidly, without trouble; allows patient to get back to his work soon, and, on account of the shortness of the wound, there is little or no danger of a post-operative hernia, even if the wound were left open, as is sometimes done in suppurative cases.

The writer has been able to remove an infected appendix in an adult successfully through less than an inch incision, and in cases of acute appendicitis, with diffuse peritonitis without adhesions, has, through about a two and one-half inch incision, excised the appendix, withdrawn all infected intestines, etc., to the surface; removed all septic matter, shreds, etc., from the peritoneal cavity and the surface of the bowels, then, after irrigation and sponging, returned the intestines, used drainage, had good recovery, and no hernia post-operative.

In all cases the appendix should be removed, if this can be possibly done without interfering with the life of the patient. If, after a careful search for the appendix, one is unable to locate it within the peritoneum, by making an incision through the posterior layer of the peritoneum external to the cæcum it may be detected behind the peritoneum, whence it can be readily removed. At times, during operations, one finds the appendix reduced to nearly a fibrous cord and buried in extensive adhesions; such a fibrous cord, being located in the normal position of the appendix, should not be overlooked by the operator, but should be excised close up to the cæcum after the method already described by the writer. Sometimes at an interval operation, on account of extensive and firm adhesions and the deep location of the cæcum and adjoining coils of intestines, it is impossible to find the appendix unless irreparable damage is done in searching for it. In such a case the wound should be closed and an operation performed later on if appendicitis again develops, and at the second operation the appendix, being inflamed, can be readily located and excised.

When adhesions are present they should always be freely separated as far as possible, as the results subsequent to operations in many cases depend upon the restoration of the normal intestinal movements.

When a local or general infection of the peritoneum is present an abscess cavity or cavities should be freely opened, adhesions, when present, be broken up, all pus shreds, etc., cleaned out, all inflamed or thickened omentum excised, the appendix removed, the abdominal cavity further examined, to be sure that no purulent mass has been overlooked. All pathological intestines, until normal bowels are seen and freely handled, should be withdrawn from the abdominal cavity to the surface and covered with hot towels. The infected portions of abdominal cavity and exposed intestines, etc., should be freely irrigated with hot water or hot saline solution, as hot as the hands can stand, and all pus, shreds, etc., removed with irrigations, sponges, and the fingers until all pathological materials are removed, and until the fluid used as irrigation comes away clear. The intestines are then dried and returned to the abdomen to, as near as possible, their normal positions.

This method of treatment should always be used in infected cases, and the operation thus performed has been found by the writer to be uniformly successful; whereas, if simply an incision had been made, pus evacuation and sponging and ordinary irrigation done, the result would have been, in all probability, just the opposite.

After these extensive operations on septic cases the wounds should be closed, as far as possible, by sutures, and the cavities or spaces of infection drained with borated gauze wicks or strips, which are carried to the bottom of the infections, the ends being brought out, as far as possible, in a direct line to the abdominal surface.

In order to obtain the full benefit of capillary drainage, the ends of the strips must be placed in contact with absorbent gauze on the surface outside of the wound, and this gauze must be changed and fresh gauze replaced when it becomes saturated to the point of decreased power, as otherwise it will have little mechanical effect. Adhesions wall off the wick or other drainage apparatus in the peritoneal cavity in about thirty hours, when the gauze or wick is shortened or entirely withdrawn, according to the indications presenting. The writer, as a rule, does not withdraw it entirely until the fifth day. The object in proceeding thus is to allow the intestine to come together as rapidly as consistent with safety, and thus obliterate the cavity formed by the wick or wicks. After this, if further drainage be necessary, carry a narrow strip of guttapercha tissue or gauze into the wound. A wick or gauze strip long enough to rest on the posterior abdominal wall adjusts itself nicely, is soft, causes no shock, and is easily removed. After its complete removal from the wound, drop in several minims of sterilized balsam of Peru, which facilitates healing and prevents sinus formation. A fecal fistula will not form from the use of a wick or strip, nor will adhesions follow its use, but some may if gauze packing, tubes, etc., are used for drainage. The writer prefers the wick or gauze strips to other methods of drainage. Guttapercha tissue around the rolled gauze has several advantages over plain gauze strips, etc.—that is, convalescence is more rapid, less painful, fewer disagreeable local symptoms; while the wick covering prevents adhesions between the gauze and serosa [R. T. Morris].

The length of time the patient is confined to bed when drainage is used is not much increased, except in those cases wherein fecal fistulæ form. The duration of confinement, after an operation in which drainage is required, is lengthened only the time it takes for the cavity to obliterate up to the skin surface, and the latter to become firmly and durably cicatrized. The writer insists that patients in whom drainage is used should remain in bed for about one week after the wound has firmly healed. This is done in order to obtain a very solid cicatrix, and thus lessen the chances of hernia. If a single wick or gauze strip has been used as a drain and the balance of the wound has been sutured accurately in separate layers, such a small opening is left after its removal that the layers fall fairly close together, and unite about as well as if they had been sutured. Hernia, under most circumstances, does not develop after the use of such a drainage method.

From a study of the pathology, etc., of appendicitis, the writer draws the following additional conclusions to those he has already published:

1. That, as appendicitis is strictly a surgical disease, the earlier it is operated upon the better for the patient.

2. That cases operated upon early should have no mortality.

3. That during all appendicitis operations the appendix should be removed, provided irreparable damage is not done in attempting to find or remove it.

4. That where there is a local or general infection the abscess cavity or cavities should be freely opened, all adhesions separated, all pus, shreds, etc., cleaned out, all inflamed or pathologic omentum excised, and all pathologic intestines and infected portions of abdomen be freely irrigated with hot water or hot saline solution till the fluid comes away clear; the intestines, etc., are then dried with sponges and returned to their normal positions.

5. That fecal concretions are more apt to be present as exciting causes of appendicitis than foreign bodies.

6. That foreign bodies are sometimes present in the appendix, and are exciting causes of appendicitis.

7. That when the appendix contains foreign material it is more likely to be a pointed or heavy body.

8. That fecal concretions closely resemble some foreign bodies of light weight; *i. e.* grape seeds, cherry stones, etc.; and that when one is in doubt whether the material is a concretion or foreign body, it should be carefully examined microscopically and chemically to determine the exact characters.

9. That operations, such as appendicitis or somewhat similar operations, *i. e.* those involving laparot-

gery, can be as readily, quickly, safely, and cheaply performed at the patient's home as elsewhere.

THE DISADVANTAGES OF GAUZE PACKING IN APPENDICITIS WORK *

By ROBERT T. MORRIS, M.D.

NEW YORK.

If we take ten strong and healthy policemen from the street at nine o'clock this evening and put half a yard of gauze into their abdominal cavities, under the most careful antiseptic precautions, we shall find by nine o'clock to-morrow evening that "we did not get them in time." It is common practice in the surgery of different countries to-day to ask weak and suffering appendicitis patients to bear what cannot be well borne by the ten strong policemen. The chief steps in the questions of abdominal drainage lead, perhaps, from chaos to Mikulicz, from Mikulicz to Tait, and from Tait to Clark, and the later school of operators, who aim at disposing of artificial drainage devices altogether in their abdominal work. Not long ago it was common practice to give opium freely after abdominal operations; the lymph circulation of the peritoneal channels was not generally taken into account in our problems, and we were all at sea on the matter of drainage. Mikulicz concentrated attention upon the idea of obtaining gross cleanliness of infected peritoneal areas, and the consensus of surgical opinion was soon in favor of the employment of gauze packing for the purpose of keeping infected surfaces apart, and for the purpose of draining septic fluids away from the wound rapidly. The employment of gauze packing was a rude method for obtaining the desired result, but it represented the best knowledge that we had at that time, and it marked a transition stage toward our later and more rational and scientific methods.

When iodoform was added to the gauze, we added another element of distress for the patient, along with certain indisputable advantages offered by the iodoform. At this moment patients in various parts of the world are dying of insidious, avoidable, iodoform poisoning, and their anxious surgeons are supposing that the cases are ones of unavoidable septicemia. Iodoform poisoning is apt to be so insidious and its symptoms so much like those of septicemia, that few house surgeons, at least, are accustomed to differentiate the symptoms. There is one pretty constant difference. In iodoform poisoning the wound is apt to look remarkably well, while the patient does not. In septicemia neither the wound nor the patient looks remarkably well. In iodoform poisoning we can find free iodine in the patient's urine, and a simple test consists in adding calomel to a specimen of the urine, and noting the reaction as iodide of mercury is formed when the mixture is stirred. Gauze packing makes trouble enough for us even without the iodoform, but only the patient can describe the distress caused by a mass of foreign body in the delicate peritoneal cavity, and only the patient can properly speak of the misery caused by the removal of the gauze packing, when a change of dressing is made. Gauze packing sometimes causes ileus and bowel obstruction by simple and direct mechanical pressure. It more often causes an excessive exudation of reparative lymph, which may result in annoying peritoneal adhesions and life-long discomfort for the patient. Its employment usually leaves a very weak place in the patient's abdominal wall, and invites the development of postoperative ventral hernia. The worst feature of gauze packing, however, is its tendency to do what any other foreign body would do in the same place. It depresses the patient's general resistance, and prolongs, if it does not sometimes cause, the condition of surgical shock. A depressed patient does not call out his resistance forces promptly, and does not retain his normal cell resistance. By resistance forces I mean chiefly the production of phagocytes for the special purpose of meeting infection. The production of phagocytes is a natural vital process, and just like other normal vital processes in its demands for an abundance of vital energy for the best accomplishment of its specific work. If a depressed patient cannot manufacture other cells well, it is fair to assume that he is not manufacturing phagocytes well, and if he is not manufacturing phagocytes well, he is not meeting infection well. It is not necessary to enter into the details of the phagocyte theory, or to quote opposing theories. For our practical surgical purposes it is sufficient for us to know that if we follow the idea of aiding the phagocytes, something within the patient acts just as phagocytes would be expected to act, and our statistics offer such testimony that physiologists may take the testimony into account in their arguments.

While surgeons, generally, were approving of gauze packing as the best means at their disposal for helping out their plans against sepsis in dangerously-infected abdominal wounds, Tait was working on quite independent lines, and achieving such remarkable results that we all felt pretty uneasy about him and his work. Many kinds of explanation were given for Tait's success without the aid of asepsis, and while many of the explanations were plausible enough to give us comfort during a conversation, the old ache came back again as soon as the explainer was out of hearing. Neither Tait nor any of the rest of us, so far as I know, had a true understanding of the reasons for his success at that time, but now it is all very clear. By means of rapid and dexterous work, Tait usually caused a minimum degree of disturbance of the patient's vital functions, and the result was a maximum degree of response on the part of the natural-resistance factors. This was such a marked feature of his work that he was obtaining better results without the aid of asepsis than some of us were getting with the most painstaking attention to details in long-drawn-out operations, which missed nothing in the way of perfection in method, so far as we could see. The most skilful artist is the one who can paint a tree so that it looks almost like the original, and still the old tree continues to look just a little better than the painting after all, and in our work it is the best surgeon who can come the nearest to leaving the patient alone with his natural-resistance forces. We conscientiously tried to do too much with our gauze drainage. The study of natural-cell resistance, and of the lymph circulation of the peritoneum were well under way when Clark struck the note that set in vibration the harmonies of our newer knowledge that were all ready to respond. Many of us were trying to convince ourselves by experience and against the teaching of the schools that we could close most of our abdominal wounds without drainage, even in cases of very extensive infection, with less danger to the patient than would follow the employment of gauze packing, or even of tubular drainage. After the publication of Clark's statistics, we felt safe in doing what experience was already showing could be done safely, and yet the closure of the abdominal wound in a case of gangrenous appendicitis was opposed to common practice and theory. The new theory was that if we removed the chief part of the toxic collection the lymphatics and leucocytes would attend to the rest better than we could do it with most complicated devices. There are cases in which some drainage apparatus must be employed for obtaining gross cleanliness of the wound. Sometimes, for instance, there is a continued oozing from separated adhesion surfaces, and of such extent that it is better to put in a small capillary drain. Sometimes the infected peritoneum is secreting serum so rapidly and abundantly that it seems to be necessary to lead off the serum externally by means of a drain, but one which is so small that it will not cause the patient discomfort, and will not interfere with a practically complete closure of the wound of the abdominal wall.

---

*A paper read before the Surgical Section of the New York Academy of Medicine, February 1[illegible], 1902.

It is not safe to teach that gauze packing is to be given up at once. It is too closely a part of the methods of to-day. It is better to say that one should work toward the point of giving up gauze drainage as rapidly as experience proves that it can be done safely. The conservatism of surgeons is an outcome of the best of human intention, and yet it works out in ways that are obstructive as well as protective. The statistics of surgeons who do not employ gauze packing in appendicitis work are sometimes read as meaning that selected cases are being reported, and not the class of severe cases in which gauze packing is commonly employed by others. The statistics have even been turned to an operator's discredit, on the ground that he must have removed some normal appendices, in order to have so low an average death rate. This is reading statistics backward, and on the wrong line as well. As a matter of fact, most of the responsible men in the profession are dealing with about the same kinds of cases all of the while, for the reason that the source of supply is through the general practitioner, and the general practitioner is apt to send only the best-marked type of appendicitis cases for operation. The differences in the statistics of various operators is therefore a matter to be given the most grave consideration, and the questions bearing upon the influence of the methods employed must be squarely met, and not evaded.

Poison Sent by Mail.—A woman named Klump, of Lowell, Michigan, received a supposed sample of headache powder by mail. She took it and died twelve hours after. An autopsy showed that strychnine poisoning was the cause of death.

A PLEA FOR SPECIFIC PLANS OF TREATMENT OTHER THAN BY SINGLE DRUGS.*

By LOUIS FAUGÈRES BISHOP, A.M., M.D.;
NEW YORK CITY.

In connection with this extraordinarily interesting topic of specifics in medicine, I wish to call your attention to the consideration of the point that there are many conditions for which a specific remedy is lacking, and for which none can be expected, where there are complete plans of treatment that are as satisfactory in those conditions as the specifics are in the correction of the diseases to which they are applicable. Indeed, close analysis of one's active hospital work for a single day would reveal the fact that a large proportion of the cases were ones outside of the realm of disease capable of treatment by specifics. Just as in diagnosis, we are too prone, in these days, to depend lazily upon the laboratory worker for information, so in therapeutics we are waiting too inactively the multiplication of specifics by those who have been lifted upon a pedestal by the prominence given them during the last century by experimental pathology. A well-thought-out and well-developed plan of treatment is as certainly specific in many a form of disease as single remedies which are known as specifics. Quinine does not, by any means, even save the life of every case of malaria, and the failures of mercury and the iodides in syphilis are only too well known.

The cold-bath plan of treatment in typhoid fever, properly carried out, is, I believe, in proportion to the dangers of the disease, as much as a specific. The same is true of proper food and bismuth in diarrhœa in children, milk diet and prolonged rest in acute nephritis, stomach rest in ulcer of the stomach, or isolation and forced feeding in melancholia. If specifics in medicine were sufficiently multiplied, it might be possible for the rule-of-thumb man to be a physician, but for the present it is the latter's task to formulate a plan of treatment that shall be, as near as possible, a specific in every case.

Science has contributed a few specific drugs. Art, with the help of well-known remedies, has given us many specific plans of treatment. In the excitement of the new discoveries of science during the last century, the art of medicine, which consists in the summoning of many expedients for a common end, has not been cultivated as it should. To be sure, improvement in nursing by trained nurses has, in a measure, replaced the necessity for the exercise of the finer details of technique in the care of the sick by the physician. The specific drug can be administered and the patient cured, and but little credit is due to any except the discoverer of the drug. But the cure of disease by a specific plan of treatment is a matter of skill more than of mere learning, and is not to be successfully carried out by the ignorant or careless. To formulate a treatment for disease that will become actually specific when developed to its highest degree, presupposes a knowledge of diagnosis and a power of prognosis that enables the physician to lay down a definite plan. Thus, in a case of acute nephritis of a certain type cure is obtained by prolonged rest in bed on a milk diet, and is completed by a short residence in a proper climate. During this time drugs are used to accomplish certain purposes, and a cure can be promised. This is a specific plan of treatment, and yet to put it through requires knowledge and firmness, of no low order, on the part of the physician. In the same way, in cardiac disease there are plans of management that are specific in that they reserve to the individual the enjoyment of all the advantages of health at the cost of compliance with certain rules of conduct, and the carrying out at intervals of certain courses of treatment. In the long run much more is accomplished by the profession for humanity by specific plans of treatment than by the specific remedies. It has sometimes seemed to me that it was a disadvantage that we had these specifics, because it makes us dissatisfied with the labor required to devise and carry out specific plans of treatment which, in the broad range of their applicability, are of vastly more importance to humanity.

---

*A paper presented to the Medical Association of Greater New York, February 10, 1902.

By specific treatment we mean the plan of treatment which is appropriate to a single disease, and is usually successful in its cure. Specific plans of treatment constitute the true art of medicine. When physicians have devoted themselves to the cultivation of specific plans of treatment, there have developed skilful practitioners, and peace and happiness have reigned in the profession. On the other hand, general principles have been detrimental to the true medical art. When physicians have subscribed to general principles, whether the humeral theory that prevailed so long, or the theory that most diseases were due to venous congestion, which led to universal bleeding, or the theory that like cures like, which led to blind faith in drugs, or that all disease was to be cured by exciting inflammation somewhere else, which led to blisters and purging, or whatever dogmas were adopted, the attempt to make facts and experience conform to general principles has always been detrimental to medicine. At the present time there is danger that there may be too much waiting for serums and antitoxins to the neglect of skilfully-elaborated therapeutic plans suitable to particular disease.

The indictment against Christian Science, Osteopathy, Viteopathy, etc., which represent, at the present moment, the mysticism that has been so detrimental to medicine throughout the ages, is not that they are not useful as forms of practice in certain cases, but that they attempt, as did our forefathers, to make facts conform to theories.

We must, in medicine, more than in any other science, hold fast to the inductive method. Facts must be the foundation of theories. The deductive method, when allowed full swing, has universally been detrimental to our profession. It held back German medicine for many years, so that even now, in spite of their many brilliant recent results from the inductive method, intelligent observers still hold that American physicians are, as they express it, better doctors. The success of this nation has been founded upon the inductive method of taking facts as they were found, and building up from them. Our most accomplished physicians have studied specific plans of treatment for each particular condition, and have been guided by facts instead of compelling these facts to stand by some supposed general principle.

This Academy of Medicine, in whose building we meet this evening, is founded upon the principle of the acceptance of medical truth as represented by specific plans of treatment as opposed to the adherence of any general principle, however plausible and however great the number of its adherents.

Our discussions will surely be without profit unless we carry from them lessons applicable to our work from day to day and from hour to hour, and just as many others will laud the discovery of specific drugs or antitoxins, so I would plead for better specific plans of treatment for every diseased condition that we must meet, and for which we must prescribe.

Looking back now over ten years of general practice, I cannot but compare the methods of those under whose influence I was prepared. Our teachers were essentially pathologists and diagnosticians. So much time was given to this part of the work that but little was left for the careful study of therapeutics of the case. Treatment was a good deal a matter of routine and tradition, and was not applied with that hopeful belief in it that I have since often encountered in less scientific men, who have devoted themselves to the cultivation of specific plans of treatment in connection with large private practices. I would except one of my teachers who is to take part in this discussion. He always had a therapeutic plan and a therapeutic suggestion for every case that might arise, and, in giving it, carried the conviction to his pupils and to the patients that what they were about to use would do a real good.

What might well be termed the Iodide-of-Potash School of Therapeutics—that is, those who administer drugs on general principles, really shows a tendency to reversion to that very state of medicine when everything was governed by supposed general principles, and which did so much to retard true progress.

What we need in order to improve our therapeutics is more co-operation among those who have the opportunity of testing therapeutic plans. We need some means whereby civil-service principles may be applied to the selection of remedies. This Association should invite those who have charge of hospital services to test impartially certain plans of treatment for, say, six months, and then to compare and analyze each other's results. The great trouble with medicine is that each man works too much alone, and is in contact only with the immature minds of younger men. While we are waiting the results of experimental pathology, which has become a thing apart from the work of most of us, let us devote our energies to the development of specific plans of treatment as something of importance in itself, and apart from all theory and the attempt to make facts conform to any system of medicine.

54 West Fifty-fifth Street.

WHAT IS CHRONIC RHEUMATISM?

By EDWIN M. MERRINS, M.D.
NEW YORK CITY.

LITTLE more than a century ago the term "Rheumatism" was so comprehensive as to include not only every painful inflammation of joints, ligaments or muscles, but also such widely dissimilar conditions, as phlebetis, pyæmia, neuralgia, tuberculous affections of the joints, and even puerperal arthritis. With the advance of medical science one disease after another has been withdrawn from this group and classed elsewhere, yet the term chronic rheumatism still covers a large number of complaints that have nothing in common except pain in some joint and a history of exposure to atmospheric change. In a recently published paper (*American Medicine*, January 4, 1902), the opinion is strongly held that cold and wet, by injuring the skin, are responsible for nearly all forms of arthritis, "from the short-lived muscular rheumatism up to the full-fledged gouty arthritis." But these etiological factors are generally regarded at the present time as of much less importance than formerly, and the diseases which they are supposed to originate directly are very few. Even the prevalent belief that rheumatic diseases are much more common in damp localities than elsewhere has no strong foundation. The report of the British Medical Association upon the geographical distribution of these diseases, states unequivocally that the degree of moisture in any locality has little or no influence upon their occurrence (*British Medical Journal*, January 19, 1889;

and *Ib.* May 19, 1900). Suppose it were otherwise, that rheumatism of a certainty is more common in marshy districts, so also is malaria, and as the latter disease is now positively known to be due to the presence of microorganisms in the blood, introduced through the agency of the mosquito, analogy would lead us to think that the former also is caused by germ infection and not by atmospheric or telluric influence. In fact, working from this point of view, many of the arthritic diseases have been found to be directly or indirectly due to this cause. Thus the diseases in which arthritic inflammation forms a primary and essential part of the disease, such as acute articular rheumatism, dengue, Malta fever, and glanders, are definitely known to be of microbic origin. The secondary affections of the joints, that not infrequently occur in the course of the acute infectious diseases, scarlet fever, typhoid fever, smallpox, gonorrhœa, puerperal fever, pneumonia, and the rest, must also be regarded as due to the invasion of the joints by the germs which have caused the general disease.

There are other bacterial diseases with arthritic manifestations in which the connection which undoubtedly exists between the germs and the arthritis is not quite so evident, because the interval between the earliest stage of the disease and the time when the joints become affected is often very considerable; and during this intervening period, sometimes lasting for many years, the patient may apparently be in the best of health and experience nothing to remind him of the taint in his system. Thus rheumatoid pains may be common in the secondary stage of syphilis, but it is not until the tertiary stage has been reached that the joints are involved in hyperplasia, gummatous infiltration or fibrous pseudo-ankylosis. So also in leprosy, after the eruptive stage has ceased to be active, or when there is no further deposit in the nerves, the disease may remain stationary for a number of years, and then among the latest manifestations of the disease, destructive changes take place in the joints.

It is not necessary to aver that in all the diseases mentioned the arthritic affections are due to the living activities of the germs, for Wasserman, in investigating the pathology of gonorrhœal arthritis found that the gonococci perish in the closed cavities of joints for want of an acid medium, but that in their dead bodies there is a virulent poison, which is the cause of the local inflammation, fever, and pain.

Among the remaining arthritic or muscular complaints that at one time or another have been grouped with rheumatism are gout, rheumatoid arthritis, and muscular rheumatism. Whatever may be the true theory of the pathogenesis of gout, all agree in attributing the arthritic manifestations of the disease to the irritant qualities of the sodium biurate deposited in or upon the tissues of the joints. The pathology of rheumatoid arthritis is still obscure, but according to the researches of Bannatyne and others, the disease is due to a specific germ. Even muscular rheumatism, that often seems to be caused by cold and nothing else, is considered by Adler (MEDICAL RECORD, March 31, 1900) to be of similar origin.

So far all is reasonably clear. Excepting gout, every arthritic disease considered has been found to be due either to the living activities of germs, or to the toxins which they produce in the system, or to both causes combined.

But when we come to the numerous cases still classed as chronic rheumatism there is much confusion; the etiology and pathology of this condition are as obscure as the ordinary treatment of it is unsatisfactory. One of the latest attempts to define the range of the diseases covered by this name is that made by Garrod in Allbutt's "System of Medicine" (Vol. III., p. 56), who groups the cases to which the name of chronic rheumatism is more or less correctly applied under three heads, as follows: (1) Frequently occurring slight articular attacks in rheumatic subjects; (2) Cases of chronic abarticular rheumatism, a condition best seen in children; (3) Joint lesions which persist after an attack, or succession of attacks, of acute or subacute rheumatism, and in some instances lead to permanent damage of the structures involved.

This is a long step in the right direction, for the term is limited to those cases in which there is a more or less clear history of acute rheumatism. But every physician must surely bear witness that from many of the patients complaining of chronic rheumatism, with symptoms in no whit differing from those in the first and third divisions of Garrod's classification, it is impossible to obtain a history of acute rheumatism, no matter how far back we go, nor how broadly we interpret the symptoms of that disease. Take the case of an actor compelled to appear on a wintry evening upon the stage in classical costume with the shoulders bared, who complains later of chronic rheumatism in his right shoulder, without any fever or the visible signs of local inflammation. He may talk glibly about his system being full of uric acid, but no amount of questioning will obtain from him a clear history of an attack of acute rheumatic fever or of anything resembling it. He has been dosed to the utmost with salicylates, and his diet has been cut down almost to the starvation point, without his deriving the least benefit. He is not gouty, nor is he afflicted with rheumatoid arthritis; neither is he syphilitic, and he is not suffering, nor has he recently suffered, from any of the acute infectious diseases. We cannot by any ingenuity bring this case within the above classification, yet we call it rheumatism brought on by cold and exposure, and add imperfect metabolism as the more remote cause. If, however, we had more closely questioned him as to his past history, we might have elicited the fact that some years previously he had had an attack of some acute specific infection, *e. g.* gonorrhœa. The discharge has ceased a long time ago, nevertheless, the pain and stiffness of the shoulder may owe its genesis to the long past infection. The following is a case in point—not quite parallel, because the urethritis has never been cured, but sufficiently so to show the dependence of the one complaint upon the other:

C. B., aged forty-two years. Family history negative so far as gout and rheumatism are concerned. Eleven years ago the patient had a severe attack of gonorrhœa, which, in spite of prolonged treatment, was never cured. The discharge would at times diminish in quantity, but any sexual imprudence or indulgence in alcohol would make matters as bad as they were at first. Three years after the original infection, the patient began to experience pain and stiffness in his ankles, this being much worse in the one that had been previously weakened by an injury. Later, intense pain developed in the sacro-iliac articulations, and occasionally there were twinges in the shoulders. Now, the connection between these rheumatic pains and the gonorrhœa is proven by the fact that when the urethral discharge is very free, the pains in the joints become so much lessened as to be almost negliplace when the tenderness is seemingly cured, the pains return with great severity.

We have already seen that all diseases of bacterial origin are capable sooner or later of producing arthritic symptoms either by the presence and activities of living germs, or by the chemical action of the toxins which they have formed. Perhaps the converse is equally true, that every form of arthritis (except gout, the neural arthropathies* and those due to traumatism) is due directly or indirectly to the action of germs and their products. When a synovitis or arthritis occurs during the febrile course of an acute infectious disease its dependence upon germ infection is plainly seen, but when the arthritic symptoms do not appear until after a long period of apparent health, and then only when the tissues have been weakened by cold or injury, their dependence, in some measure at least, upon the long past bacterial infection is either overlooked or denied. Yet, as we have seen, in both syphilis and leprosy, many years may elapse between the time of infection and the time when the joints become affected. May it not be—and this is the main point of the paper—that in every case of chronic rheumatism, if we closely inquire into the past history, we shall find that at some time or another the patient has had some disease of microbic origin, in women generally acute articular rheumatism, influenza, typhoid fever, or some uterine disease † affecting the whole system, in a large proportion of men either gonorrhœa or syphilis, more frequently the former?

Examining the personal records of thirty-seven recent cases, with a history of pain in one or more joints, it is found that four were due to traumatism, in two cases with painful ankles and feet the patients had flat feet, four were afflicted with rheumatoid arthritis, and six were distinctly gouty. In the remaining twenty-one cases, all complaining of chronic rheumatism or of an excess of uric acid in the system, there was a previous history in five cases of acute articular rheumatism, in one of small-pox, in eight of gonorrhœa, in two of syphilis, one was tuberculous, and in four of the cases no statement upon this particular point was obtained. This is to be regretted, for, considering their occupation, it is almost certain that from three out of the four a history of specific infection could have been obtained by close and persistent questioning. However, taking the figures as they stand, it is surely very significant that in twenty-one cases of pain and stiffness in one or more joints, and indistinguishable, so far as gross appearances go, from each other and from the ordinary run of rheumatic cases, no less than seventeen patients gave a history of having previously suffered from some disease of microbic origin.

This is quite in line with the clinical observation of others. Leri in his article on Rhizomelic Spondylosis (*Revue de Médecine*, September 10, 1899), which many regard as a form of intervertebral rheumatism, in considering the etiology of this disease states that "the most satisfactory explanation is that it arises in an infection; several patients had gonorrhœa shortly before it began, and other infectious diseases had been seen in other cases, and grip, tonsillitis and other mild affections are so frequent that they seem the most likely cause." Sachs and Fraenkel, in a careful article discussing the different types of the disease, adduce four cases of their own, of which the first had had an attack of influenza, the second syphilis, the third "at the age of fifteen years had a fever which kept him in bed for two weeks, lost his hair and became bald," the fourth syphilis (*Journal Nervous and Mental Disease*, January, 1900). These cases are the more noteworthy as the etiology of the disease is not considered in the article.

Where so many cases of chronic rheumatism have been preceded by acute infectious disease, the conclusion is irresistible that the two are connected, that the joints in all such cases must have been attacked during the course of the primary disease. Our inability to obtain a clear history of this may be owing to the fact that the arthritic symptoms were so light as not to have attracted attention during the manifestation of the more urgent symptoms. Thus in several cases of pneumonia slight redness and pain have been observed in the shoulder joints of the affected side, which subsided with the crisis; it has been noticed in other cases that such arthritic symptoms may precede the lung symptoms, follow the crisis, or develop intercurrently (Nathan Raw, *British Medical Journal*, December 21, 1901). The patient's attention having been confined to the condition of his lungs, it is not likely he would remember such a minor symptom as slight pain in some joint.

What then bridges the gap between the acute infectious disease and the appearance months or years later of rheumatic symptoms? An observation of Adami may throw light on this point. Speaking of Metchnikoff's researches in phagocytosis, he says, "that the seizure and incorporation of microbes by the phagocytes do not necessarily lead to the death of the former, so that in certain cases of acute disease there may be abundant phagocytosis and the disease progresses nevertheless; the phagocytes being destroyed by the products of the incorporated organisms. . . . In other less acute diseases, such as gonorrhœa, and in chronic maladies of a tubercular nature—in tuberculosis, leprosy and glanders—the bacilli may in certain stages be found within the cells and rarely free in the lymph spaces; they appear to be almost parasitic after the manner of the microsphæra previously referred to as infesting the amœba. In these cases it would seem as though the toxic properties of the microbes and the antagonizing powers of the cells are very nearly balanced, and this equality, or almost equality, of the resisting powers of the cells and microbes may explain the chronic nature of the diseases above mentioned" (Allbutts' "System of Medicine," Vol. I., pp. 83, 84).

The germs, therefore, which had invaded a joint during the course of an infectious disease would upon the patient's recovery be forced into quiescence, and would remain so as long as this balance of power between the tissues and the germs was maintained. As soon, however, as the resistant power of the tissues become weakened by cold and wet—which are thus seen to be secondary, not primary, etiological factors—the balance is destroyed, and the symptoms of pain, stiffness and weakness follow. If Wassermann's theory be established that the toxins and not the germs are the cause of the local arthritic trouble, the conclusion is practically the same.

Walsh, in his very interesting paper upon this subject (*American Medicine*, November 30, 1901), is of the opinion that toxins circulating in the blood are the cause of the various arthritic symptoms. This may be so when they occur during the course of an acute disease, but many chronic rheumatics, apart from the pain and stiffness in some joint, feel very well, indeed, both mentally and physically, which is difficult to explain if toxins are present in the blood stream to any appreciable extent. But if, as now claimed, the source of the complaint is local, the absence of constitutional symptoms in most cases is satisfactorily explained. So also is the resemblance of such cases to each other, for there is no reason to suppose that in their action upon synovial membrane and cartilage the various germs and the toxins elaborated by them differ very much from each other, whether such action be vital, chemical, or physical.

---

*It would seem that the arthritis of gout, undeniably caused by the deposition of a foreign chemical substance in the tissues of the joints, does not in its nature differ very much from a similar joint trouble due to the presence in the tissues of toxins. As for the arthropathies of such a disease as locomotor ataxia, so large a proportion of cases have a syphilitic history as almost to warrant its inclusion in the group of toxæmic arthropathies.

†See, for example, "A Quiet Effusion into the Knee-Joints Occurring in Women and Young Girls," *Lancet*, February 23, 1901.

If these views should be further confirmed by the results of pathological investigation, the term chronic rheumatism ought to be applied only to those rare cases in which there is a clear and unbroken connection with an attack of acute rheumatic fever. We shall then be enabled to make a simple and clear classification of joint affections, as all arthritic manifestations of disease can be placed according to their pathogenesis in one or other of the following divisions, or combinations of them: (1) Traumatism; (2) Bacterial infection; (3) Toxins and other chemical irritants; (4) Nerve degeneration.

A SIMPLE TEST FOR EQUILIBRITY OF EYE MUSCLES IN BINOCULAR VISION.

By FRED'K C. RILEY, M.D.,
NEW YORK.

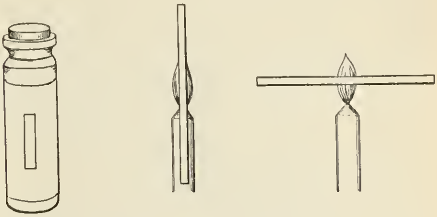
Every practitioner of medicine has, at varying intervals, patients complaining of headaches, neuralgias, etc., dependent upon lack of equilibrium of the muscles of the eyes in binocular vision. Many such are referred to the oculist immediately for examination, while not a few are subjected to various therapeutic measures.

It not infrequently happens that patients can ill afford the time and attendant expense of an oculist's examination, or feel that they cannot, unless they are assured that they will benefit thereby.

Any physician can, at no expense and with but little trouble to himself, be prepared to express an opinion with certainty regarding this condition of his patient without any special preparation for ophthalmic work.

During the past few years great advance has been made in the recognition and correction of lack of equilibrium of eye muscles in binocular vision, which, when present, develops most distressing symptoms. The determination of muscular equilibrium is a simple process, and any deviation can be readily ascertained by the family physician in the following way, which is in reality a modification of the Maddox rod. This rod of Maddox gives such a small image that it cannot be used advantageously under all circumstances. The cylindrical lens, as advised by Prentice ("Ophthalmic Lenses," pp. 121), is in itself expensive, and most of us do not always have rod or cylinder at hand. The same results can be obtained by the use of a homeopathic medicine vial filled with water, or, preferably, any red-colored liquid.

The vial should be surrounded by paper, upon both sides of which an opening has been left. These openings must be opposite each other. The patient is now seated before a lighted candle, placed on a level with his eyes, distant twenty feet or thereabouts. Hold the vial containing the red liquid in front of his eye, perpendicularly, and he will see a red band of light; the distorted image of the candle flame, due to the cylindrical shape of the vial, passing horizontally to and fro as the vial is moved laterally. If the vial be held in front of the right eye, he sees a red band with the right, and the yellow white light of the candle with his left eye. He cannot fuse the images into one, for they are too dissimilar, consequently we have an opportunity to study their relationship. Provided the red band passes through the candle flame as the vial is slowly moved from right to left, it shows that the eyes act harmoniously in the vertical plane. Provided it appear above or below the true candle flame, it shows a lack of equilibrium, *i. e.* one eye fixes above that of its fellow, and a so-called hyperphoria exists. Having recorded the conditions of examination thus far, turn the vial at right angles and move it gently up and down, and note the lateral deviation of the two lights. If there be no deviation—the red band passing through the candle flame—lateral equilibrium exists. Holding the vial horizontally before the right eye, if the red band appears to the right of the candle flame it evidences esophoria; if to the left, exophoria. The distances between the lights measure the degrees of the deviation, as two and three-eight inches (6 cm.) of variation, at twenty feet (6 meters) of distance between eye and candle flame requires a prismatic lens of one prism diopter to correct it, be it lateral or perpendicular.



Thus we prescribe prisms of sufficient "strength," combined with spherical or cylindrical lenses to neutralize any existing refractive error, to secure perfect binocular vision.

No new principle is here involved, but I have endeavored to make this test so simple that any one can make it, even if the patient is confined to the bed. Such findings are also very useful, from a diagnostic and prognostic standpoint, in connection with the history of each case.

STATIC WRINKLES.

By HENRY G. PIFFARD, M.D.,
NEW YORK.

After a very unsatisfactory experience with a couple of static machines made in a Western city, I exchanged the last one for a product of home talent. The machine was of the usual construction, with eight revolving thirty-inch circles. The output of electricity was reasonably good, and little fault could be found except that the plates would not hold the charge over night, frequently losing it in a few hours. This machine was shortly replaced by another of the same make, warranted not to balk; but balk it did as badly as the first one. I then suspected some local "hoodoo," as both of the machines were reputed to hold their charges properly when in other hands. The hoodoo was finally located, and its influence obviated by the simple expedient of putting glass insulators under the legs of the case.

In nearly every machine that I have seen, the shelf that supports the jars has a central re-entrant curve. In other words, the shelf will support simply the jars, and but little else. This shelf I replaced with one having the curve reversed and thus secured a convenient rest for such subsidiary apparatus as from time to time, I might desire to use.

The large five or six-inch globes that constitute such a salient feature of most machines may be useful as well as ornamental, but their particular field of usefulness I have never been able to discover. I, therefore, removed them from their customary position and transferred them to the upper front corners of the case, where they are equally ornamental. A couple of small vulcanite balls, one inch in diameter, occupy their former place. I cannot detect any difference in the current.

In using Morton's wave current with a spinal electrode and an eight plate machine, I early became satisfied that a stronger current would be of distinct advantage. This was gained by adding two revolving plates, thus increasing the output over 25 per cent. This difference in the current was very noticeable, due, firstly, to the increased generating surface, and, secondly, to the diminished internal resistance, as the plates had to be brought nearer together, so as not to occupy more space than the original eight. Up to this time the spark gap, usually employed by myself and recommended by others, has been about five or six inches as a maximum.

In the course of some experiments, having nothing to do with the administration of the wave-current, I substituted a seven-inch metallic disc for the small trial ball on the end of the negative pole-rod. The changed character of the spark led me to make a trial of this arrangement with the wave current. The result greatly surprised me, as I found that I could use a spark gap of ten inches or more with no more inconvenience to the patient than formerly with the five-inch gap. The spark was not only twice as long, but apparently thicker, and the immediate effect more pervasive; that is, the vibrations were felt over a more extended area. As the strength of the current and its effects on the system appear to be proportionate to the length of the spark gap, the little device here mentioned has virtually doubled the efficiency of the static machine, so far, at least, as regards the administration of the wave current.

256 West 57th Street, New York, February 25, 1902.

Surgical Treatment of Tuberculosis of the Peritoneum, Intestines, and Genito-Urinary Organs.—William H. Wathen coincides with the general opinion that laparotomy does cure some cases of peritoneal tuberculosis. He says that there is nearly a consensus of opinion that laparotomy is not indicated during the earlier stages of the disease, but again if we delay too long, until there is extensive ascites of the peritoneal structures of the bowel, the omentum, the mesentery, and general peritoneum are greatly thickened, or universal adhesions have formed, practically closing the peritoneal cavity, or numerous sacculated accumulations of pus have formed, we may have delayed too long to offer our patients the best results—the happy medium being the correct solution. In stenosis following intestinal tuberculosis the bowel has been treated by physiological exclusion, by performing an anastomosis between the healthy bowel at each end of the stricture, by complete exclusion, excising the bowel at each side of the stricture and uniting the ends by circular suturing, then closing the ends of the strictured portion and leaving it *in situ*. He endorses the conclusions of Young as to the surgical treatment of genitourinary tuberculosis as follows. (1) Epididymectomy, with high resection of the vas deferens, is the operation of choice; (2) Castration should be confined to cases in which the testicle proper is involved, or the scrotal disease is extensive. (3) Double castration should be avoided if possible, a portion of healthy testicle being left even with the risk of local recurrence of the disease. (4) Operations upon the seminal vesicles and prostate should be done only after removal of the testicular foci has failed to arrest the progress of the disease. (5) Serious involvement of distant parts—pulmonary, urinary, osseous, etc.—does not contraindicate operation. (6) Disappearance of extensive tuberculosis of the prostate, seminal vesicles, bladder, and kidneys, lungs, etc., may follow the simple removal of the testicular foci.

Carcinoma and Malaria.—I. Prochnik, as the result of his observations in the South Sea Islands, does not believe that malarial infection is of any avail in the treatment of carcinoma, notwithstanding the contrary opinion of F. Loffler. Malaria is an exceedingly common disease in these islands, and there are, indeed, very few of the inhabitants, either foreign or native born, who do not suffer periodically therefrom. Carcinoma is fairly prevalent also, but figures show that, generally speaking, it is more common among the native than among the foreign inhabitants, and this in spite of the fact that malaria is more frequent among the former than the latter. Numerous cases of carcinoma have been observed in which malaria was at the same time present, and yet never in such cases has the author observed the least benefit of the carcinomatous condition thereby. This is the universal experience of all physicians practising in these islands. In regard to the most frequent location of the carcinoma in that climate, it is interesting to note that in the vast majority of cases the liver is the seat of the disease. Thus, out of twenty-two cases observed in natives, in eighteen the liver was the primary seat of the disease. Prochnik accounts for this by the fact that liver diseases, especially cirrhosis and abscess, are very common in these islands. He believes that malarial infection is responsible for the special susceptibility of the liver to disease in that climate. Investigation has shown that oftentimes liver puncture will establish the presence of the malarial parasites when these cannot be found in the blood taken from the peripheral circulation. It seems probable, therefore, that the damaging of the liver by the malarial parasite indirectly lays the foundation for the development of carcinoma in this organ.—*Wiener klinische Wochenschrift.*

Cigarette Inebriety.—J. M. French considers the cigarette habit injurious chiefly because it is indulged in to great extent by young and growing boys, because, being small, the cigarette is often smoked almost constantly, and because it is the common practice to inhale the smoke, thus largely increasing the poisonous effects of the nicotine. Statistics prove that in Yale College the non-users of tobacco gain in weight, in height, and in chest girth, more than the regular or occasional users. The same conditions obtain in Amherst. In the Polytechnic School in France it was found that the non-smokers took the highest rank in every grade, and that the smokers continually fell behind. In an experimental observation of thirty-eight boys of all classes of society, who had been using tobacco for from two months to two years, twenty-seven showed severe injury to the constitution and insufficient growth, and thirty-two showed irregularity of the heart's action, disordered stomachs, cough, and a craving for alcohol. Within six months after they had abandoned the use of tobacco, one-half were free from their former symptoms, and the remainder recovered by the end of the year. Whatever may be the verdict with reference to the use of tobacco by healthy adults, all physicians and scientific men agree that young and growing boys should not use tobacco in any form.—*The Quarterly Journal of Inebriety.*

The Microscope as an Aid to Diagnosis and Prognosis in Chronic Suppuration of the Middle Ear.—E. F. Snydacker calls attention to the significance of cholesterin, epidermis shreds, and bone dust in the discharge from suppurating ears. Concerning the two latter elements, he says that it must not be forgotten that after a long-continued suppuration of the middle ear the mucous membrane becomes denuded in places, and such surfaces may by a reparative process become clothed with epidermis, an outcome which may be entirely favorable, and, far from indicating cholesteatomatous formation in the middle ear, is one means which nature has devised of effecting a cure. It is only when the discharge persists after this epidermis formation has begun, and when by its constant irritating contact it causes over-production of epidermis, and this is constantly cast off, as is shown by its continual presence in the discharge, that its production must be regarded as a dangerous symptom. One cannot, therefore, on a single finding of epidermis shreds, make a diagnosis of cholesteatoma or advise an immediate operation; it is only when these shreds are present and the discharge persists for weeks, and even months, that it is safe to regard them as a danger sign. It is otherwise, however, when the process has gone so far that the epidermis presents the concentric arrangement known as cholesteatoma. When we can convince ourselves that cholesteatomatous masses are present, all delay is detrimental to the best interests of the patient, and it is far better to give up the case at once, than to enter on a fruitless and dangerous treatment. As to the indications when bone dust is present, there may be a difference of opinion: if the carious bone has its source in the ossicles, and the tympanic walls and mastoid cells are intact, then there can be no danger in delay. When, however, we remember the findings of Grunert, who in 108 cases of caries of the middle ear found only two where the ossicles alone were involved, while either the tympanic walls or mastoid cells were involved in all the other cases, we must agree that where carious bone is present in the discharge, and persists after thorough treatment has been instituted, a radical operation is surely the most conservative course.—*Archives of Otology.*

Eradication of Scarlet Fever.—J. W. Ames believes that the carrying out of the following regulations will lead to an eradication of scarlet fever: (1) Every suspected case should be promptly isolated until the diagnosis can be positively confirmed; (2) After confirmation, make isolation absolute, and report the case to the Health Department; (3) Instruct the family to keep the patient isolated until all signs of peeling are invisible; (4) All members of the family who desire to leave the house must do so the first day after their clothing has been disinfected. This will take six hours, as all their apparel must be placed in a sealed room and exposed to formaldehyde gas for at least that length of time to insure public safety, and they must remain away until quarantine is removed; (5) No person should leave the infected area after fourteen days' continuous exposure, unless the sick patient is free from desquamation; (6) The attending physician should have as little contact as possible with the patient; cleanse his hands thoroughly, and disinfect his clothing before entering another house; (7) The character and duration of the isolation must be left to the Public Health Department. Thorough disinfection with formaldehyde, ten ounces to one thousand cubic feet, the germs having now been corralled, will destroy them and thus end the existence of the disease.—*Physician and Surgeon.*

The Diagnosis and Treatment of Pain in the Ear.—Macleod Tearsley says that for the intracranial complications nothing but operation can suffice. In reflex otalgia, the existing trouble—a carious tooth, disease of the tongue, fauces, or pharynx—must be sought for and treated. The two forms of external otitis, diffuse and circumscribed, must be treated practically alike. Leeches can be applied in front of the tragus; hot instillations of sterilized water, hot boric lotions, cold by the ice-bag or by Leiter's tubes to the mastoid region, or a combination of hot and cold can be used. Cocain, 2 to 5 per cent., or morphia, 1 per cent., or both combined, may be used as instillations. The furuncular form is so agonizing that a sedative must be used, few preparations being better than Battey's liquor opii sedatives, in 5 minim doses every four hours. In cases of middle-ear inflammation secure absolute rest, give a saline purge, and use instillations at a temperature of 115° F. Combine cold with it, applying the ice-bag to the region below the auricle. Leeches give the most relief. In the early stages of acute inflammation of the middle ear the process can often be aborted by careful use of the Eustachian catheter.—*Treatment.*

Résumé of the Subject of Actinomycosis, with Report of a Case of Actinomycosis Abdominalis.—A. Vander Veer and Arthur W. Elting discuss this infectious disease, common to man and many of the domestic animals, and caused by a polymorphous fungus belonging to the genus of oöspores. The consensus of opinion is that the great carriers of the actinomycotic contagion are the different forms of cereals, especially barley. The neoplastic type is the one usually found in horses and cattle, and the inflammatory type in man and hogs. Poncet and Berard classify the forms of the disease as the cervicofacial, thoracic, abdominal, and cutaneous. The duration of the disease is from a few weeks to several years. In abdominal actinomycosis (of which the authors report a case), there are three typical periods: The initial period, in which the symptoms often resemble recurrent appendicitis; the period of tumor formation; and the period of fistula. The discharge from the fistulæ may be serous, seropurulent, or purulent. A fourth period of repair, or cicatrization may be added. Medical treatment alone does not seem to be very successful. The surgical treatment of all cases amenable to operation should be practised, in combination with large doses of potassium iodide. —*Albany Medical Annals.*

The Structure and the Physiological Significance of the Hæmolymphatic Glands.—Egidio Morandi and Pietro Sisto conclude that these glands, which are found in the region of the lymph glands, assist in the formation of lymphocytes and in the destruction of changed red blood cells. This conclusion they have reached, because (1) Of the presence of globuliferous cells containing red corpuscles in progressive stages of disintegration; (2) After destruction of the spleen, the number of globuliferous cells in the hæmolymphatic glands is enormously increased; (3) Because in animals deprived of their spleen, the administration of hæmolytic substances still further adds to the production of these cells; (4) Because the authors were unable to find any nucleated red cells or giant cells possessing any hæmatopoietic functions; (5) The injection of pyrogallic acid, while inducing acute anæmia of a severe type, did not cause hæmatoblastic activity in the hæmolymphatic glands at all on a par with that shown in the spleen after bleedings had rendered the bone marrow incapable of supplying the necessary number of red cells.—*Archivio per le Scienze Mediche.*

Cheyne-Stokes' Respiration, and Associated Phenomena. —E. Grande reports a fatal case of fractured skull, in which, ten days before death, there was typical Cheyne-Stokes' respiration, with absolute immobility of the chest. The period of apnœa was about forty seconds, that of dyspnœa from fifteen to twenty. There was no modification of the pupils, nor movement of the eyes during apnœa. The pulse became very irregular, and almost too rapid to count. There was abolition of reflexes and total unconsciousness. Injections of caffein diminished the duration of apnœa, and induced a more regular type of breathing. The Cheyne-Stokes' respiration appeared precisely at the time when the medulla oblongata became involved by pressure of the fractured temporal bone, causing disturbed circulation with diminished nutrition. The author considers this form of respiration as of little diagnostic or prognostic importance, unless accompanied by other significant symptoms.—*La Riforma Medica.*

Medical Record:

A Weekly Journal of Medicine and Surgery.

Publishers

WM. WOOD & CO., 51 Fifth Avenue

New York, March 22, 1902.

THE SANITARY SERVICE OF THE ENGLISH ARMY

The severest critics of the Army Medical Department of the British Army are to be found in Great Britain itself. The strictures, passed unsparingly by civilians upon every detail connected with the Army Medical Corps in South Africa, have given the general public of Great Britain and journals of Continental Europe much cause for the belief that the whole army medical organization is lacking in the essentials that go to make up an efficient service.

On no one point have the detractors, both native and foreign, been more agreed, than that the lack of a good sanitary system has been responsible for the enormous death rate from typhoid fever, and it has been constantly urged that the appointment of sanitary officers, with special powers, would have prevented the spread of the epidemic.

The truth would seem to be that the British authorities were at fault in allowing the medical service to become unpopular, and consequently undermanned, by refusing to allow its members the privileges which were, undoubtedly, their due, but so far as the work of the medical department in South Africa has been concerned, it has been performed, on the whole, efficiently.

Many eminent army medical authorities doubt the wisdom of appointing special sanitary officers. Military exigencies are against such a course, and, as is pointed out, a goodly portion of an army medical student's curriculum is devoted to the study of hygiene.

Captain John Stewart Kulp, Medical Department U. S. Army, who has recently paid a visit to the Army Medical School at Netley, England, has published an unbiased and appreciative review of the course of training at that school, and of the medical organization generally of the British Army.

He says that at Netley the instruction in hygiene is both practical and theoretical, is admirable in its thorough comprehensiveness, and includes a broad, general view of the subject—its history, its civil and military objects, and the geographical distribution of disease. Care is taken to impress on the student that the highest function of the military surgeon is the prevention of disease . . . In clinical and military medicine there is bedside instruction on the more prevalent diseases of military men, together with lectures on the diseases which are modified by the habits, character, and duties of the soldier, invaliding and tropical diseases.

As to the field service of the British Army, it is allowed on all sides that, with regard to equipment, it does not compare favorably with the same service of the United States Army.

We had occasion to draw attention to this fact in the Record a short time ago.

Captain Kulp, referring to this branch of the British Army, says that while the English fully realize that an army medical department in war must be self-sustaining, and organize the force accordingly, the defects in the system are many and obvious. He enters into a minute description of the methods of the British Army Medical Department in the field, but which space fails to give in detail.

Captain Kulp says, in conclusion, that South Africa has taught England what it is to be hoped we have learned during our late war, namely, the value of an organized medical department possessing real authority in relation to all subjects affecting the health of troops. An aggregation of regimental medical services is not a medical department, and uniformity of material and administrative methods is of no greater importance than is uniformity in the education of the personnel which is to handle them.

The organization and equipment of the Army Medical Department of the United States are confessedly unsurpassed in the world, and the English might with advantage, in these respects, take example from our methods. But, on the other hand, the training in sanitary matters is much superior in the British Army to that in our army, therefore the authorities in this country should seize the opportunity of copying from the British, and of rendering the army medical department of the United States a model service throughout.

The experiences gone through by our army medical officers in Cuba, Porto Rico, China, and the Philippines, should impress indelibly upon the minds of those in control the necessity of a sanitary training and of instruction in tropical diseases for the army medical corps.

FREQUENCY OF TRICHINOSIS IN THE UNITED STATES

The belief is current that trichinosis in man, occurs but seldom in the United States. The fact is, of course, well known that trichinosis in hogs is prevalent, it having been shown, as a result of examination of pork for commercial reasons, to be about 2 per cent.

Dr. Herbert Williams, Professor of Pathology, University of Buffalo, for several years past has been making investigations into the matter, and has published the outcome of his researches in the July *Journal of Medical Research*.

Before entering upon the subject of trichinosis, as regards its prevalence in this country, the Buffalo professor gives some statistics treating of the frequency of the disease observed by various authorities some of which it may be as well to quote.

In 1855, Zenker discovered four cases of trichinosis in 136 autopsies at Dresden. According to Fiedler, writing in 1866, encapsulated trichinæ were found at 2 to 2½ per cent. of the autopsies in Dresden hospitals. Leuckart stated, in 1866, that in Berlin and Dresden 3 per cent, of all subjects contained trichinæ.

Gribbohm in Kiel, 1872-1877, in 972 autopsies found one case, 1 per cent. Wagner of Leipzic is said, by Haller, to have found trichinosis once in every thirty to forty bodies.

In Scotland 1 to 2 per cent. of the dead bodies, examined during the five years preceding 1860, are said by Turner to have contained trichinæ. Scheiber in Bukarest stated, in 1871, that in Roumania about one body in 200 contained trichinæ. In St. Petersburg, Rudnew found trichinæ three times among 150 dissections.

According to Lancereaux and Blanchard trichinosis is almost unknown in France.

Concerning the frequency of trichinosis in the United States, the following examples are cited:

In 1881, Kerber, in San Francisco, had made thirteen consecutive examinations of subjects, and found no trichinæ. Dr. Leidy wrote that he had repeatedly seen trichinæ in subjects in the dissecting room at the University of Pennsylvania, but that no record of them had been made.

Whelpley, in St. Louis in 1891, examined, with the microscope, specimens from twenty cadavers in the dissecting room, and found one case of trichinosis. Osler states that his notes show that in 1,000 consecutive autopsies trichinæ were present in six instances.

Packard was able to find, in July, 1897, that between 1864 and 1897 357 cases of trichinosis in man were known to have occurred in the United States and Canada. While, according to a communication from Stiles to Osler, in February, 1898, about 900 cases had been reported from the United States up to that date.

Dr. Williams began his investigations in 1894, during which period 505 cadavers were examined, and trichinæ were found present in twenty-seven, or 5.34 per cent. The subjects studied were selected at random, and were of various nationalities.

The percentage of cases of each nationality in which trichinæ were found was as follows:

United States, white, 2.89; United States, colored 7.14; British and Irish, 8.06; Canadian, 16.66; German, 12.24; Italian, 16.66.

As might be expected, the proportion of Germans in this list is large, but taking into consideration their reputed habit of consuming uncooked pork, their position is a matter for no comment.

The native Americans give an unexpectedly high percentage, attributed by Dr. Williams either to the fact that some of the American whites may have been of German parentage, and continued their ancestral custom of eating uncooked pork, or to the custom, occasionally followed by the farmers in New York State and in the southern parts of the United States, of taking a piece of pork from the barrel and eating it without further preparation.

The prevalence of trichinosis among the colored race is thought by Dr. Williams to be probably due to carelessness in preparing food and eating, while the large percentage among British subjects appears incomprehensible, except on the ground that a number of the bodies were procured from an insane institution, where the pigs, raised on the premises and used for food, had been decimated by a disease diagnosed as hog cholera, just before the collection of samples for Dr. Williams' work was begun.

The result of the investigations are summarized as follows: (1) Samples of muscles secured at 505 unselected autopsies on adult human subjects were examined microscopically for trichinæ. In twenty-seven cases, or 5.3 per cent., trichinæ were present; (2) All of the subjects died of other diseases than trichinosis. The infection with trichinæ must, in every case, have occurred a considerable time previously; (3) The infections were of various degrees of severity, being sometimes very extensive, and sometimes so slight that only one or two worms were detected; (4) The birthplaces of the subjects included the most important countries of North America and Europe. The number of cases was not large enough to allow accurate conclusions to be found as to the influence of nationality upon the frequency of the disease. The fact that a large proportion of cases occurred in subjects who were born and had lived in the United States is important; (5) An unusually high percentage occurred among subjects who had been insane; (6) Examination of sections from the above cases for eosinophilic cells failed to show such cells about or near the encapsulated trichinæ; (7) Mast cells do not collect in or about the capsules, in cases of old trichinosis; (8) Plasma cells occasionally appear in or about the capsules; (9) New-formed elastic fibers sometimes appear about the capsules; (10) As described by Leuckart and Langerhaus, the capsules may be invaded by new cells, the worms disintegrate, and thus the capsule become filled with fibrous and adipose tissue.

Dr. Williams' painstaking and protracted investigations have revealed two facts, that trichinosis is more frequent in this country than was believed, and that many cases of trichinosis escape detection at autopsies. Careful microscopic examination is necessary to determine the less severe forms of the disease, and consequently the presence of trichinæ is often passed by. The result of the researches at Buffalo do not prove that the disease is frequent throughout the United States, but it lends weight to the belief that such may be the case, as well as emphasizing the danger of eating uncooked pork.

Effect of Destroying the Yellow Fever Mosquito in Havana.

Constant warfare against the Stegomyia mosquito in Havana, by the Sanitary Department, has resulted in very marked diminution in their numbers. In 17,000 houses examined by the "mosquito corps," during the month of January, in only 411 were larvæ found—while, if a similar inspection had been made the year previous, larvæ would have been found in almost every instance.

As a result of this systematic mosquito destruction, not a case of yellow fever has occurred in Havana for nearly six months. Since 1889 the average annual number of deaths from yellow fever for the ten months, April 1 to February 1, has been 457.18; during the same period just passed, only five deaths have occurred from this disease. In January, a year ago, the yellow-fever infection was present in every part of Havana. In January of the present year Havana was not only entirely free from fever, but had been so for four months. The Sanitary Department has worked exclusively on the hypothesis that the Stegomyia mosquito is the sole agent by which yellow fever is transmitted, and has entirely disregarded the question of "fomites." It feels assured that this method, which has eradicated yellow fever from Havana, will keep that city free from the disease in the future. The measures of mosquito destruction employed include drainage of [illegible] removal of receptacles for standing water as far as possible, the free use of petroleum and the destruction of adult mosquitoes by formaldehyde, sulphur or the fumes of burning pyrethrum powder.

THE CLERGY AND SPIRITUALISM

The daily papers have lately exploited a divine of a fashionable church in this city who maintains that he sees ghosts, talks with them, and even receives mysterious dictations from the other world. In other words the distinguished gentleman confesses himself as a believer in visions and attempts to explain them from a purely subjective point of view.

Naturally enough, the medical profession takes issue with the reverend expounder of these absurd views. Dr Louis Albert Banks in an address delivered last Sunday before the Grace Methodist Church very pertinently said: "What folly this stuff is! I notice that a court and jury in Philadelphia have just set aside a will conveying $30,000 because they regard a belief in power to communicate with spirits to be a form of insanity. It is strange to what extremes the pendulum will swing in a man's life. In his early life Dr —— was a Methodist minister, and retired from the Methodist Church because he could not believe things in the Bible which he could not understand. And now we have him taking hold of all these wares of the spiritmongers with avidity. The sad side of this clairvoyant humbug is the pitiable state to which it reduces many fathers and mothers, whose hearts cry out with grief at the death of their children, and many who long to hold communication with dead friends. The insane asylum holds many a victim of these conspirators against the broken-hearted. They allure only to deceive, they do harm and not good. The whole story of spiritualism is stained with deception and falsehood and humbuggery." Dr Banks is perfectly right in his stand, and has voiced the sentiment of the profession in no uncertain tones.

SMALLPOX IN LONDON

No more remarkable, and to the unprejudiced convincing, object lesson of the immunity to smallpox conferred by vaccination could have been afforded than that presented at the present time in London. The epidemic is there increasingly prevalent, and since the commencement of the outbreak there have been about 800 deaths, of which 80 occurred in the week ending March 15. Fresh cases are being recorded at the rate of about fifty a day. The following figures, given in a despatch to the *New York Sun*, March 16, show the value of vaccination and the necessity for revaccination about the age of twenty. Of a total of 766 deaths, 400 were those of vaccinated persons and 292 of unvaccinated persons. Regarding seventy-four there is no definite statement; of the 400 vaccinated persons who died only forty-seven were under twenty years of age, while of the 292 unvaccinated people 224 were below twenty; of the eighty deaths in the week ending March 15 fifty-two were above twenty. As a rule, in these days when big epidemics of smallpox in civilized countries are rare, individuals who have been vaccinated in infancy do not have the operation repeated when they arrive at years of discretion, forgetting or ignoring the fact that the immunity produced by vaccination only lasts a certain period.

Of the 353 vaccinated people over twenty who have recently died of smallpox in London the great majority had not been vaccinated, probably, since early childhood, and were therefore almost as susceptible to the disease as if they had never been vaccinated. It may be hoped that the continued prevalence of smallpox in London and in other parts of Great Britain, and the valuable statistics with regard to vaccination gathered therefrom will convert skeptics on the subject in all parts of the world to a belief in the merits of vaccination as a preventive of smallpox.

AMENDMENTS TO NATIONAL HEALTH BILL

At a convention of some twenty State Health and quarantine officers, called by Dr Edmond Souchon, President of the State Board of Health of Louisiana, differences of opinion regarding proposed legislation to establish a national health department were harmonized, and unity of action secured in requesting the passage by Congress of House Bill 7,189, introduced by Mr Hepburn, and Senate bill 2,162 introduced by Mr Perkins, with a slight amendment to Section 7, authorizing a convention of State health authorities as occasion may demand whenever in the opinion of the Surgeon-General of the Marine Hospital Service such a convention is necessary, or upon the request of five representatives of State boards of health or quarantine officers. This bill gives the Marine Hospital Service jurisdiction over civil health matters. Notification of the agreement upon this bill was conveyed to the House Committee on Commerce by a delegation composed of Dr. H. M. Bracken, Secretary of the State of Board of Health of Minnesota; Dr Edmond Souchon, President of the State Board of Health of Louisiana; Dr. William H. Welch of Johns Hopkins University, Surgeon General Wyman of the Marine Hospital Service; and Dr. H. L. E. Johnson of Washington, representing the legislative committee of the American Medical Association.

Among others present at the conference were: Dr James Evans, Secretary of State Board of Health of South Carolina; Dr. A. H. Doty, Quarantine Officer, Port of New York; Dr. U. O. B. Wingate, Secretary State Board of Health of Wisconsin; Dr. Henry D. Holton, Secretary State Board of Health of Vermont; Dr. Nowber, Secretary State Board of Health of Delaware; Dr. Durgin, Quarantine Officer, Port of Boston; Dr. W. W. Sanders, State Health Officer of Alabama; Dr. Lewis of the New York State Board of Health, and many others.

WHAT THE ARMY MEDICAL DEPARTMENT HAS DONE FOR CUBA.

In his annual report for the year 1901, the Chief Sanitary Officer of Havana says:

"This is probably the last annual report that will be made by a United States Army officer, as health officer of Havana, to his military superior, the Governor of the Island, so I hope that I may be excused if I point out some of the sanitary differences between 'the then' and 'the now.'"

"The Army took charge of the Health Department of Havana when deaths were occurring at the rate of 21,252 per year. It gives it up with deaths occurring at the rate of 5,700 per year. It took charge with smallpox endemic for years. It gives it up with not a single case having occurred in the city for over eighteen months. It took charge with yellow fever endemic for two centuries, the relentless foe of every foreigner who came within Havana's borders—from which none could escape, and from whose attack every fourth man must die. It found Havana feared as a thing unclean by all her neighbors of the United States, and quarantined against as too dangerous to touch, or even to come near anything she had touched, to the untold financial loss of both

Havana and the United States. It leaves, after the careful study of the question of yellow fever by its officers, undeterred by personal risk—for several of the investigators have died of the disease, contracted at their work. It has established the fact that yellow fever is only transmitted by a certain species of mosquito, a discovery that, in its power of saving human life, is only excelled by Jenner's great discovery, and as time goes on, it will stand in the same class as that great boon to mankind. . . . It has demonstrated a system by which yellow fever can certainly be controlled without interference to commerce."

The above facts speak so forcibly for themselves that comment thereon is superfluous. The record made by the Army Medical Department in Cuba has gained for itself the admiration of the profession

Sanitary Regulation of Prostitution in Cuba

General Wood has recently issued an order announcing the appointment of a sanitary commission, composed of five well-known Cuban physicians, in connection with the regulation and control of houses of ill-fame in the island of Cuba. Very stringent laws on this subject existed under the Spanish rule of the island, but they were enforced either not at all or only in part. Popular sentiment in Cuba recognizes the fact that venereal disease is a sanitary problem, which should be dealt with by the public health authorities exactly like any other communicable diseases affecting the general welfare. The questions of sanitation and ethics are fully recognized, but the Cuban regards them as quite distinct from each other, and can see no reason why respect for ethical considerations should stand in the way of common sense dealing with a sanitary problem.

A Judge on Medical Expert Testimony.

At the annual dinner of the Society of Medical Jurisprudence, held on March 8, Judge Woodworth of the Appelate Division of the Supreme Court, responding to the toast of "Expert Testimony, as Viewed by Appellate Tribunals," passed some exceedingly caustic criticisms upon the manner in which expert testimony is given at the present time.

The judge said, in part: "That experts who told partial truths, or who, for a fee, testified for the side on which they were retained, were perjurers, who disgraced both the profession of medicine and that of law.

"When expert witnesses of the medical profession give testimony to things not scientifically true, their brothers of the profession know that before high Heaven, they have testified falsely, and if such men were treated as outcasts that kind of swearing would be a matter of the past."

The methods now in vogue of taking medical expert testimony are undeniably faulty, and oftimes lead to unfortunate results, but that medical men deliberately perjure themselves, or even withhold part of the truth for the sake of gain, is an exaggerated presentation of the facts of the case.

Of course, medical men are but human, and, like other mortals, are prone to error and to sin, but, although not saints, they are, as a body, as honorable and straightforward as is any class.

There doubtless have been instances where members of the medical profession have deviated from the straight path of truth, and have thrown dust in the eyes of the jury, for the sake of the fee, but it may be confidently asserted that such occurrences are rare.

The tendency, as an expert witness, to be somewhat biased in favor of the retaining side, is probably unavoidable, and a certain amount of partisanship, under existing conditions, will surely creep in.

The system in force, dealing with expert testimony, in the courts of law of this country, is more at fault than the witnesses, and it would be in the interests of all if radical and practicable reforms could be introduced.

The Medical Record has always held that an independent medical board should be established whose duty would be to proffer perfectly unbiased scientific, and medical testimony.

The successful solution of the problem of how to procure absolutely honest expert testimony is beset with difficulties, but the medical profession, for its own fair name, would do wisely to take steps to render it impossible for a judge to declare that many medical witnesses are not to be relied upon for the strict truth.

Alcohol in the Human System.

Professor W. O. Atwater of Wesleyan University recently delivered an address before the Hartford Medical Society on "The Nutritive Value of Ordinary Foods and Alcohol."

In speaking of the somewhat heated discussion on this point, which has been proceeding for the past two or three years, Professor Atwater referred to the fact that a number of scientists have opposed the theory that alcohol possesses a nutritive value, and have laid especial stress upon the view that alcohol does not protect protein from consumption.

It is known that sugar, starch, and fat protect the fat of the body from consumption, and the proteids also. The great majority of distinguished experimenters believe that alcohol protects body fat from consumption, but some deny this power as regards protein. This is the main point in the argument of those who declare that alcohol has no nutritive value. They contend that not only does it afford no protection to protein from consumption, but that it tends to increase its oxidization, and consequently cannot be regarded as useful for nourishment.

For some time past, the most eminent exponent of this view has been Dr. Rosemann of the University of Griefswald, Germany, and he is constantly quoted as one of the chief opponents of the nutritive value of alcohol, although lately, on several occasions, he has expressed his written opinion that it possesses such a value.

A recent issue of *Pfluger's Archiv für Physiologie* contains an article by Dr. Rosemann on the influence of alcohol upon the metabolism of protein, in which he brings out a number of new experiments made by him on the subject. He finally concludes that alcohol, in moderate doses, does protect body protein from consumption, though in some instances it temporarily fails to do so, and it may, in fact, tend to increase the amount of protein consumed. The latter effect appears to be the case mainly with individuals unused to alcohol, and with them seems to last but a short time; and, afterward, the alcohol protects protein from consumption.

Professor Atwater and other investigators coincide with these views of Rosemann.

Professor Atwater concluded an interesting address with the following words: "Science forbids our saying that alcohol is in no sense useful, or that it is always harmful, but it also demands that we should urge the great danger of excessive use." He repeated what he had often said before: "For people in health, and especially for young people, alcohol is an excellent thing to let alone."

News of the Week.

Attempted Assassination of a Physician.—Dr. Samuel Lederman of this city narrowly escaped being killed by a bullet fired last Sunday morning by Abe Spinner, who, brooding over the death of his child, attempted to kill the physician whose treatment he believed was responsible for the death of his son. A hot-water bath was used by the physician and the child being slightly burned the father insisted that the burns were the cause of death. The physician, however, was exonerated, both by the Coroner and by the civil courts. The fact that the City Court had dismissed Spinner's suit seems to have made the salesman frantic, and while in this state he attempted the life of the doctor. The bullet, fortunately, lodged only in the clothing of the physician.

Smallpox Victims.—According to the official reports of the Marine Hospital Service, there were 22,263 cases of smallpox in the United States during the week ending March 15.

This is an unusually large number, and the officials are somewhat concerned about it. For the same period last year only 9,416 cases were reported. The deaths from smallpox during the last week have been 661, as against 136 for the same week of last year, the number being almost quintupled.

Jesty's Claim to Jenner's Discovery.—In the *London Standard* of a recent date occurs the following: The late Mr. C. Jesty, Magistrate of Antwerp, Weymouth, England, brother of Mr. A. Jesty, sends the following extracts, held documents relating to B. Jesty's discovery of vaccination. These words are copied from a graveyard in Worth Maltravers churchyard. "Sacred to the memory of Benjamin Jesty of Downsbay, who departed this life April 16, 1816, aged 70 years. He was born at Yetminster, in this county, and was an upright, honest man, particularly noted for having been the first person (known) that introduced the cowpox by inoculation, and who, from his great strength of mind, made the experiment from the cow on his wife and two sons in the year 1774."

The Late Prof. Paul F. Mundé.—At a meeting of the Medical Association of Greater New York, held at the New York Academy of Medicine, March 10, 1902, the following report of the Committee on the death of Dr. P. F. Mundé was adopted: "The Medical Association of Greater New York desires to give expression to the loss it has sustained in the death of its associate, Dr. Paul F. Mundé, one of its founders and most distinguished members. In his professional life and work he exhibited the attributes of the conscientious and conservative physician, and throughout his whole career, in every position he occupied, discharged its duties with fidelity and devotion, winning the respect and esteem of all who knew him. Our deepest sympathy is extended to his afflicted family, and we hereby resolve that this note be entered in our minutes, and a copy be sent to the family.

(Signed) W. H. KATZENBACH, M.D.
HENRY C. COE, M.D.,
CHAS. F. ADAMS, M.D.,
Committee.

Brooklyn Medical Club.—Prof. E. W. Scripture of Yale University will deliver the annual lecture of the Brooklyn Medical Club at the Medical Library Building, 1313 Bedford avenue, March 24, 1902, at 8.30 P.M. His subject will be "A Chapter from the New Psychology: Recent Researches on the Voice," with the exhibition of lantern slides, experiments, and other illustrations.

$500 Damages for Autopsy.—Mrs. Annie Botsford obtained a verdict of $500 against the Presbyterian Hospital before Justice Gildersleeve of the Supreme Court because the hospital authorities performed an autopsy on the remains of her husband, Albert Kent Botsford, without authority from her. The verdict is said to be the first of its kind in this State. The institution does not perform autopsies without consent of the relatives, and it set up that a brother of Mrs. Botsford had given this consent. The court would not permit evidence to this effect on the ground that the widow was the only one who could give the authority.

The American Congress of Tuberculosis will be held at the Hotel Majestic, on May 14, 15 and 16th proximo. There will be, aside from all papers of a miscellaneous nature, four symposiums, arranged each to occupy one session of the body, viz. (1) Preventive Legislation, Embracing the Social, Municipal and State Aspects of Tuberculosis, (What aid should be expected from the State in the cure and prevention of tuberculosis, and how shall this be secured?) (2) Tuberculosis in Its Pathological and Bacteriological Aspects, (3) The Medical and Surgical Aspects of Tuberculosis (Embracing Sanitoria and Climatic Conditions, Light and Electricity); (4) The Veterinary Aspects of Tuberculosis. Professor Adami will speak at the Congress, and Professor Koch of Berlin has been invited to contribute his views.

Association of American Physicians.—The seventeenth annual meeting of the Association of American Physicians is to be held in Washington, D. C., on April 29 and 30 and May 1, 1902.

A New Psychopathic Ward.—The trustees of the New York Infirmary for Women and Children have, through the influence of Dr. Alexander Lambert, established in connection with the infirmary, a psychopathic ward with two laboratories for neuropathology and psychopathology. Dr. Alexander Lambert is the Chairman of the Committee of the Trustees.

The purpose of the psychopathic ward and laboratories is the study and treatment of nervous and mental diseases, especially of the initial stages of pyschomotor degeneration and of borderland cases of mental alienation.

The Board of Attending Physicians consists of the following gentlemen: Dr. Alexander Lambert, Dr. Carlos F. MacDonald, Dr. Frederick Peterson, and Dr. Pierce Bailey.

Dr. Ira Van Gieson is appointed Director of the Neuropathological Laboratory, Dr. Boris Sidis is appointed Director of the Psychopathological Laboratory, and Dr. George M. Parker is Assistant in Psychopathology. Dr. Henderson B. Deady is to take charge of the administrative part of the ward.

Health Board Objects to Compulsory Vaccination.—The Board of Health, on March 13, adopted a resolution against compulsory vaccination, as proposed in Assembly Bill No. 1,439, introduced by Assemblyman Fuller. This bill gives power to the State Commissioner of Health to compel vaccination in any county when it is, in his opinion, necessary.

Smallpox in City Jails.—Smallpox has appeared in the Tombs, and it is also said to have occurred in two other city prisons. Every precaution is being taken by the Health Department to prevent the spread of the disease.

The American Association of Urologists was organized on February 22, 1902, essentially for the purpose of further development of the study of the urinary organs and their diseases. The annual meeting will be held on the last day and the day following the annual meeting of the American Medical Association. The officers of the association are: Ramón Guiteras, M.D., *President;* Wm. K. Otis, M.D., *Vice-President;* John Van der Poel, M.D., *Treasurer;* Ferd. C. Valentine, M.D., *Secretary;* A. D. Mabie, M.D., *Assistant Secretary.*

A Jail Quarantined.—Smallpox in the White Plains Jail has brought business in all the county offices to a standstill. It was learned that two more prisoners had contracted smallpox. Guards patrol around the jail, and no one is allowed within 200 feet of the main entrance. A guard-house has been erected in front of the jail.

Coroner Archibald T. Banning has been selected by the Supervisors to have complete charge of the arrangements. All the patients will be taken to the county poorhouse at East-view.

Smallpox in London.—The returns of smallpox for the week ending March 1 show the following figures: On Saturday, February 22, there were 42 fresh cases notified and removed; on Sunday, 23, there were 25 fresh cases; on Monday, 24, there were 53 fresh cases; on Tuesday, 25, there were 63 fresh cases; and on Wednesday, 26, there were 44 fresh cases.

Berlin Board of Health Regulations for Vaccination.—1. Vaccination in infancy, renewed at the end of childhood, renders an individual practically as safe from death from smallpox as if that disease had been survived in childhood, and almost as safe from attack.

2. The duration of the immunity conferred by vaccination is variable. In many individuals vaccination in infancy and revaccination in childhood is sufficient for life protection. In a limited number immunity is lost in five or six years. It is never possible to know with certainty to which class an individual belongs. In the face of an epidemic, therefore, vaccination of all who have not been vaccinated within five or six years is giving what the lawyers call the benefit of a reasonable doubt. Every one who has been vaccinated in infancy and childhood should be vaccinated not less than once in adult life.

3. The immunity conferred by vaccination is in direct proportion to the thoroughness with which it is performed, and this is shown with considerable accuracy by the character and number of the resulting scars.

4. Vaccination in infancy alone is not sufficient wholly to prevent smallpox among the adult population.

5. Optional vaccination has not proved sufficient to protect the community from smallpox. Compulsory vaccination is a measure warranted by more than a century of experience.

6. The mild compulsion enforced in this country by requiring vaccination, or evidence of its recent performance, upon admission to the public schools, should have the hearty support of parents and physicians alike.

Children's Seashore House at Atlantic City.—New buildings for this life-saving charity, to occupy an entire block in the city by the sea, and costing $120,000, are in process of construction, and it is expected will be ready for occupancy in June. The main structure is three stories high, with a basement, 132 feet long by forty feet deep, and it is supported by two wings, all facing the ocean, and placed on a line 200 feet back from a specially constructed breakwater. When completed, the institution will accommodate 325 mothers and children. In addition to children requiring sea air, special dietary, skilled nursing and medical care, young women under twenty are also admitted, and youths under eighteen can join a seaside camp on the beach. It is hoped that in the future it will be possible to keep the institution open throughout the year as a sanatorium for convalescent children from the city hospitals.

Passage of Safety Pin per Anum.—Dr. Wm. Herbert Bell of Cincinnati, O., writes: "Noting the case of gastrotomy, reported by Dr. John T. Howell of Newburgh, N. Y., in the MEDICAL RECORD of March 8, 1902, I would like to report the following:

"A child, one year and three days old, E. J. M., was brought to my office two hours after having swallowed an open safety pin one inch long, and at its widest part, when open, five-eighths of an inch. I concluded to take chances and let nature assert itself, advising nothing to be done that night, except giving it its milk, and an hour after its morning feeding to give a large tablespoonful of castor oil. The pin was passed Saturday morning, March 8, two days after the oil had been given. The only pain or inconvenience suffered was on swallowing the pin and on its exit through the sphincters.

"On account of the child's health, it being a very puny and diminutive one of its age and bottle fed, I desisted from the method described by Dr. Howell in the treatment of his case, as I believed that the acids of the stomach might so corrode the pin as to cause it to be more readily encased in the milk, and took the chance that it would pass the right way."

College of Physicians of Philadelphia: Section on General Medicine.—At a stated meeting, held March 10, Dr. Augustus A. Eshner presented "A Case of Arthritis." He dwelt upon the necessity of differentiating rheumatic from rheumatoid affections, both acute and chronic. The case presented was that of an unmarried woman, thirty-one years old, who presented swelling of the metacarpo-phalangeal joints of the hands, yielding a sense of elastic fluctuation, which had been present for a number of years. There was some grating on movement, and also some wasting of the muscles of the hands, and a general appearance suggestive of deforming arthritis. Dr. W. T. Longcope exhibited "Wright's Coagulation tubes," consisting of a series of graduated pipets, in which measured amounts of blood are exposed to the heat of water at the temperature of the body until clotting takes place. Dr. A. O. J. Kelly reported "A Case of Mediastinal Tumor," in which, for a long time, there had been present symptoms of bronchitis. The detection of retrosternal dulness and the appearance of a nodule over the sternal extremity of one clavicle suggested the diagnosis of lympho-sarcoma, but histologic examination of the removed gland disclosed the structure of an adeno-carcinoma. Death took place, but no autopsy was permitted. The possibility of the stomach being the primary seat of the disease was considered, in spite of the fact that the symptoms referable to this viscus were comparatively insignificant. Dr. Herman B. Allyn reported "A Case of Perforative Appendicitis with Abscess; Operation; Recovery." Drs. David Riesman and Louis N. Jacob read a paper entitled "Spontaneous Pneumothorax, with the Report of a Case Ending in Recovery in a Man Aged Twenty-seven Years."

To Improve the Sanitary Conditions of New Orleans.—New Orleans has an unenviable reputation for the unsanitary state in which a large proportion of its population live. This is especially the case with its negro inhabitants. Efforts are now being made to effect reforms in this respect, and negro preachers and citizens are taking steps in that direction to see whether something cannot be done to [illegible] the negro there has been a death-rate double that of the whites. A course of lectures on hygiene is to be delivered for the benefit of the negroes, and negro ministers will preach on sanitary matters. The New Orleans Board of Health will make a general examination of the premises of the city inhabited by negroes and enforce the sanitary laws rigidly.

Philadelphia Pediatric Society.—At a stated meeting held March 11, Dr. John Lovett Morse of Boston delivered an address on "Some Diseases of the Kidneys and Bladder in Infancy." He described the characters of the urine passed by the new-born and nursing infant, and recited the results of observations bearing upon the frequency with which albumin is found present. It is only by such systematic examination that diseases of the genito-urinary can be detected, as the development of other symptoms, and especially edema, cannot be depended upon. At the close of the meeting a reception was tendered Dr. Morse.

Spiritualism and Mental Unsoundness.—There seems to be sound judgment in the verdict of the jury in a Philadelphia court in setting aside the will of a man who had bequeathed the residue of an estate of $35,000 to an Association of Spiritualists. The will was contested by a daughter of the decedent on the ground that her father was of unsound mind and under the influence of Spiritualists. For the defence it was contended that the decedent was not of unsound mind, and that his belief in Spiritualism was as reasonable as the opinions of many on religious and social subjects.

Public Baths.—The movement in favor of public baths in the densely crowded parts of New York continues to gain strength. Several meetings have been held in support of this much-needed reform, and the administration will be expected to fulfill the pledges it made before election, that public baths should be established to be open both in winter and in summer.

Samaritan Hospital, Philadelphia.—Ground has been broken for an annex, consisting of an administration building, fifty feet square, one story high and basement, in which there will be an office and large reception room. It and the clinic building will be connected with the present hospital by a wide corridor. Adjoining, on the north, will be a three-story-and-basement structure, forty-two feet by eighty-five feet. This will contain wards, baths, nurses' rooms, diet kitchen, and storerooms.

Wills' Eye Hospital, Philadelphia.—According to the report of the Board of City Trusts, the equipment of this hospital is described as antiquated, its buildings dingy and out of repair, and new buildings unfinished. It is said that the income from the Wills' estate is not sufficient for the running expenses. The sum of about $5,000 is required to place the hospital in proper condition at the present time.

Philadelphia County Medical Society.—At a stated meeting held March 12, Dr. Hugh H. Young read a paper entitled "The Diagnosis and Treatment of Calculus of the Lower End of the Ureter in the Male." Dr. Chas. P. Noble read a paper entitled "The Treatment of Suppuration in the Uterine Appendages." He dwelt upon the good results that he had secured in a certain group of cases, by means of vaginal puncture and drainage, in preference to abdominal section.

Gift to Harvard Medical School.—Dr. J. Collins Warren and Dr. H. P. Bowditch have announced that Mrs. Collis P. Huntington has given $250,000 to the fund for the erection, equipment and endowment of the New Harvard Medical School.

This sum makes up the $4,050,000 considered necessary for the intended school, and renders immediately available the proposed gift of three buildings at a cost of $1,000,000 by J. P. Morgan, and a gift of $1,000,000 promised conditionally by J. D. Rockefeller.

Pathological Society of Philadelphia.—At a stated meeting, held March 13, Dr. Robert N. Willson presented a communication entitled "A Case of [illegible] Double Infection Without Secondary Anemia." Drs. G. E. de Schweinitz and E. A. Shumway presented a communication entitled "The Lesions in a Series of Eyes Which Produced Various Types of So-called Sympathetic Disturbances in the Fellow Eye." Drs. L. W. Steinbach and D. Riesman exhibited specimens from "A Case of Acquired Hydronephrosis." Dr. D. Riesman exhibited "A Renal Calculus of Calcium Carbonate, Calcium Oxalate and Magnesium Phosphate." Drs. H. A. Hare and R. C. Rosenberger exhibited a specimen of "Aneurism of the Thoracic Aorta." Dr. A. O. J. Kelly exhibited microscopic sections of a specimen of "Diffuse Primary Carcinoma of the Kidney," with metastases in the lungs and the liver.

The Prevalence of Plague in Australia.—It is announced that plague is prevalent in Melbourne and Sydney, so much so, indeed, that several prominent theatrical companies have canceled their Australian tours as a result of cable advices from Australia, telling of the malady.

Measles on the Increase.—The epidemic of measles which has been prevalent in New York since the commencement of the year, shows no sign of abating. The records of the Department of Health show that the number of cases reported in each week from February 1 to March 1 was as follows: February 1, 706, February 15, 962, February 22, 987, and March 1, 1,105.

In Support of the Metric System.—The House Committee on Coinage, on March 13, directed a favorable report to be made on the bill providing for the adoption by the United States of the metric system. It provides that after January 1, 1904, all departments of the Government in the transaction of all business requiring the use of weight and measurement, except in completing the survey of public lands, shall employ and use only the weights and measures of the metric system; and after January 1, 1907, the weights and measures of the metric system shall be the legal standard weights and measures of and in the United States.

The Most Practicable Organization for the United States Army in Active Service.—It is announced from the Surgeon-General's office that the time limit for submitting the essays on the above subject, in competition for the Enno Sander prize, has been extended to March 31, 1902.

Much interest is being taken in the matter and the competition promises to be an interesting and active one.

Mortality of Michigan for January, 1902.—There were 2,824 deaths, exclusive of still births, returned to the Department of State for the month of January, 1902, an increase of 105 deaths over the number returned for the preceding month. The death rate was 13.5 per 1,000 population. There were 442 deaths of infants under one year of age, 197 deaths of children aged one to four years inclusive, and 910 deaths of elderly persons aged sixty-five years and over.

Important causes of death were as follows: Tuberculosis, 18; typhoid fever, 45; diphtheria and croup, 39; scarlet fever, 34; measles, 24; whooping cough, 19; pneumonia, 378; influenza, 64; Cancer, 125; accidents and violence, 147. There was a slight increase in the number of deaths from pulmonary tuberculosis and pneumonia, and a considerable decrease in the mortality from diphtheria and croup, as compared with the preceding month.—*Michigan Monthly Bulletin of Vital Statistics.*

Division and Bureau Reports of Chicago Health Department for the week ended March 1, 1902: Laboratory—Bacteriological examinations made of ice, water, meat, and milk, 39; for suspected disease, typhoid, diphtheria, and tuberculosis, 64; outfits prepared for diagnosis of the same, 450; distributed diphtheria antitoxin, 59 vials; glycerinated vaccine, 2,330 tubes.

Contagious diseases—Total number of cases, 245: Diphtheria, 55; scarlet fever, 170; smallpox, 2; measles, 7; typhoid fever, 1; others, 1; disinfections performed, 127.

Public Baths—Total number of baths given for the week, 5,383. Milk Bureau—Of the 299 samples of milk and cream analyzed 134 were brought to the laboratory by private individuals, the remaining 265 were collected by the milk inspectors; of the 265 inspectors' samples ten were tagged "Skimmed Milk," and 203 not tagged, therefore sold for whole milk; of these, six were found below grade; out of fifty-three samples of cream, two were found below grade; 3 per cent. of inspectors' samples of milk were found below grade.

American Doctors in Brazil.—The New York *Tribune*, March 11, has the following:

"Under date of February 1, Consul Kennedy writes to the State Department from Para, Brazil: There is a federal statute in Brazil which provides that all physicians, surgeons, and dentists of foreign extraction who desire to practice their profession in any part of the country must first pass a prescribed examination at the medical colleges at Bahia and Rio Janeiro. These examinations, which include language and other branches not usually found in a medical curriculum, are said to be so severe that few foreigners have any chance of passing them successfully. It is now reported that this law is to be more rigidly enforced hereafter, especially in the case of dentists. There are several American dentists in Para who have been practising there for years. They may be required to go to Rio Janeiro and take examinations, and in case of failure they will be compelled to give up their professions, or leave the country. Although this is a very profitable field for medical practitioners, it should be remembered that the examinations are so severe as to compel two or three years' extra preparation."

Discharged Naval Medical Officer Likely to Be Reinstated.—Dr. Edward Kershner, who was dishonorably dismissed from the United States Navy on March 21, 1896, has almost succeeded in being reinstated. A bill, restoring him to his former rank of Medical Director, and giving him full arrears of pay, has passed both houses of Congress, and will be, in a short time, it is believed, signed by President Roosevelt.

Insurance After Smallpox.—After smallpox the British income-tax underwriters are now offering to insure against an increase in the income tax, and quite a number of policies have been issued.

Improvement in Teeth Forceps.—J. B. Davis of New Orleans has recently invented an improvement in the way of forceps for dentists' use which will greatly reduce the cost of the outfit which a dentist is compelled to purchase. His invention consists of the forcep handles, into which can be slipped beaks, which are readily detachable. Mr. Davis says this set is intended more for the use of students and country doctors who pull teeth, and to such persons his device will practically give the advantage of a full dental equipment at a very much reduced cost.—*Scientific American.*

Intoxication Among Women.—According to the report of the Department of Vital Statistics, drunkenness among the women of London is increasing year by year. This is, perhaps, one of the reasons why the Government is rigorously enforcing all clauses of the Government licensing bill that gives discretionary powers to Justices to suppress drunkenness as far as possible.—*New York Herald.*

Water of Chicago.—The weekly bulletin of the Health Department of Chicago, for week ended March 8, draws attention to the contamination of a part of the supply of Chicago's water by the Calumet. The Calumet, when the ice broke, began to pour into the lake the accumulated filth of the winter's work of the packing industries, refineries and other foul waste-producers along its banks, which was carried by the wind up to the Hyde Park Crib. Between February 1 and March 8 the water from the Lake View tunnel averaged 100 per cent., good or usable; that from the four-mile tunnel, 99.8 per cent.; from the Carter Harrison and the Chicago avenue tunnels, 93.3, while the Hyde Park supply was only 56.6 per cent., good or usable, during these thirty-six days, and on more than one occasion it was positively poisonous.

The Hyde Park tunnel supplies more than 40 per cent. of the total area of the city and contains about 20 per cent. of the total population. The remedy for this state of things is said to be comparatively simple. It involves a reversal of the flow of the Calumet from the lake into the main drainage channel by pumping through the old "Sag Feeder," and a provision for the discharge of storm waters from the Calumet water-shed into Lake Michigan, somewhere well east of the State line beyond the zone of pollution. In the meantime persons supplied with water by the Hyde Park tunnel are advised to boil it before drinking.

Vital Statistics of San Francisco for January.—Total number of deaths in San Francisco in January was 749, of which general diseases claimed 304, local diseases 381, and violent deaths 64. The births registered during the same period were 470. Comparative statement of deaths by months for the six months preceding January, 1902, was, for July, 530; August, 478; September, 516; October, 566; November, 564; December, 586; Comparative statement of births for the same period was, for July, 400; August, 459; September, 499; October, 500; November, 510, and December, 470.

Bazaar in London in Aid of Hospital.—A fashionable bazaar, says the *New York Herald*, will be that in aid of the Hospital for Sick Children, Great Ormonde Street. The Queen is to open it, and many Americans will take an active part. Mrs. John Mackay has endowed a bed at the hospital in memory of her son. The American section of the bazaar will include four stalls and an American bar. Mrs. Choate is interested in the undertaking.

State of New York Assembly Bills.—Two bills relating to public health were introduced into the New York State Assembly on March 6, read once, and referred to the Committee on Public Health. The first, introduced by Mr. Fisher, is intended to amend the public health law, relative to local boards of health, and contains a considerable amount of new matter, some of which might be adopted with advantage. The second bill, introduced by Mr. Fuller, is also a suggested amendment of the public health law, relative to local boards of health, but concerns itself solely with the management of and precau tions to be taken in the case of contagious and infectious diseases. The bill recommends the enforcement of general vaccination by local boards of health of all persons, when required to do so by the State Commissioner of Health, who is authorized to make such requirement when in his judgment such action is necessary for the protection of the public health.

Caring for Street Accidents in Paris.—According to a cable dispatch to the *New York Herald*, a novel and ingenious apparatus for rendering first aid to the injured in street accidents was tested this week in Paris. It resembles a pillar letterbox, and contains a small medicine chest, folding stretcher, and telephonic communication with the nearest ambulance station. Access is obtained by breaking a glass panel.

Paris Druggists Barred from Prescribing.—The right of pharmacists to diagnose the ills of their customers and prescribe accordingly, has been successfully combated in the Paris courts by the Physicians' Protective Association. A test case was brought against a druggist who, after analysis, prescribed for kidney trouble. Although the diagnosis and treatment were shown to be correct, the druggist was fined fifty francs (ten dollars) and costs.

Campaign Against Tuberculosis in Havana.—Major W. C. Gorgas, Surgeon, U. S. Army, Chief Sanitary Officer of Havana, is engaged in active measures looking to the diminution of tuberculosis in that city. Information as to the nature and care of this disease is being generally spread among the population by lectures, printed matter, etc. So far 1,642 cases of tuberculosis have been located within the city limits, and their names and addresses carded and arranged for easy reference. Estimating the life of a tuberculosis patient to average about three years, and multiplying the number of deaths from this cause (900) during the past year by three, Major Gorgas estimates that there are about 2,700 cases of tuberculosis in Havana at the present time. The average number of deaths from this cause, per year, since 1890, has been 1,555.00, while for the year 1901 it was reduced to but 900. It remains, however, the chief factor in the death rate. Major Gorgas is pushing a scheme for the establishment of a public sanitarium for the tuberculous, located near Havana, which has received the support of General Wood. This sanitarium is to be divided into two sections. Of these, one devoted to incurables will be located at Hospital No. 1, on the outskirts of the city, while the other will receive patients in whom the disease appears to be curable, and will be situated about five miles out in the country. Negotiations are now under way for the purchase of a hundred acres of land at the site selected for the latter, and work will be pushed as soon as a title can be secured. The sanitarium will be supported by the Cuban Government, and will be entirely free to those unable to pay their way. The sanitarium is established, in the interests of public health, with the idea of getting as many as possible of the infected poor out of the crowded tenement houses—particularly the bed-ridden poor, who are a great source of infection under present conditions. The establishment of the projected sanitarium is expected to be of great assistance in diminishing tuberculosis; though the Sanitary Department places its chief dependence in securing this result in urging an improvement in the home care of patients with tuberculosis, and in the constant teaching of patients and their friends the simple sanitary measures that will so certainly prevent the spread of the disease to those about the patient.

Correspondence.

OUR LONDON LETTER

(From Our Special Correspondent.)

MEDICAL COUNCIL AND ROYAL COLLEGES—MIDWIVES' BILL—APPENDIX VERMIFORMIS—[illegible]—SYPHILOLOGY AND CANCER—LATE [illegible]—DINNER OF MEDICO-CHIRURGICAL SOCIETY.

London, February [illegible], 1902.

The General Medical Council has this week held a special meeting to consider the question between it and the two royal colleges as to the first year of the curriculum. The committee appointed for the purpose presented a report with recommendations. These latter were withdrawn by consent, and the report only adopted. A resolution was passed that the examinations of the Conjoint Board be inspected and the colleges requested to give further information as to the schools they had recognized and which the Council did not approve. Reading between the lines, we may see that a compromise was arranged for the Council to take the first step. Some say it will hold out the olive branch which the colleges will grasp. Others smile or sneer, and say the Council is a past master in the art of climbing down. But what could be expected of a body composed almost entirely of representatives of the corporations? The President congratulated the Council on showing it could do things in a businesslike way when it made up its mind to do so!

On Wednesday the Midwives' Bill was got through the second reading in the House of Commons, and was sent to the standing committee on law. Sir J. Batty Tuke moved its rejection, and pointed out that it would not reduce the number of uncertified midwives, as its supporters pretended, for the penal clause of the bill of 1900 had been omitted. But the Home Secretary supported the bill on the ground that if it did not remedy the evil, which most people admitted, it tended to lessen it. A committee of the medical council will endeavor to secure amendments.

The appendix vermiformis monopolized the attention of the Clinical Society on the 14th inst. Mr. Gilbert Barling opened with a paper on seventy-four cases of inflammation with localized suppuration in the right iliac fossa or immediately adjacent to it. These cases were a portion of 145 operated on in the acute stage. In forty-six of the seventy-four the abscess, though well shut off by adhesions, had not reached the parietal peritoneum, and operation involved opening the general peritoneal cavity. Mr. Barling held that the abscess should be attacked as soon as the diagnosis of suppuration is made, but it must be remembered that pus may be present with normal temperature and pulse, though other symptoms indicate it. Leucocytosis is not pathognomonic, but very valuable; it was only absent in two cases out of twenty-one. The safety of treating without removing the appendix was shown by the low mortality. There were only two deaths in the seventy-four cases.

A paper was then read by Mr. F. C. Wallis on the treatment of intraperitoneal abscess of the appendix illustrated by eight cases. He dealt with cases in which the abscess is shut off from the general peritoneal cavity, but not adherent to the abdominal parietes, and it was, therefore, necessary to open the cavity before dealing with the abscess. All the patients but one were young, and adhesions at this age are frail, and require delicate manipulation to prevent the pus escaping. To prevent this, gauze sponges were packed in a crescent about the affected area, and when possible the pus gradually evacuated and sponged up as it appeared. When the tension and amount of pus was too great for this, the patient was tilted over to the side and the pus caught in a small bowl as it escaped. The appendix was removed after the cavity had been cleansed. Iodoform packing was used, the wound being kept as dry as possible. Early operation after the first attack was urged.

Mr. A. G. Barker thought it best to remove the appendix at the first operation if it could be done easily, if not, to remove it in the quiescent period which followed. He favored washing out the abscess cavity with saline solution and effective drainage by an "aseptic apron." Instead of incising the muscles, the fibers should be separated, by which room could be obtained to evacuate the abscess—a great benefit for the patient.

Mr. J. Berry thought it was not advisable to remove the appendix in all cases. He waited till adhesions had formed, and then made a small opening. In forty-one cases thus treated only two died. In thirty-nine cases in which extensive operations were done thirty-two died. During the last five years, at the Royal Free Hospital, out of fifty-three cases in which he had waited for adhesions he had forty-nine recoveries and only four deaths. He quoted statistics from other hospitals.

Mr. Cuthbert Wallace gathered from St. Thomas's Hospital reports that there was a recurrence in 5.5 per cent. of localized abscess cases.

Mr. Spencer urged that the abscess should be opened as soon as pus was diagnosed. He was for removing the appendix at the first operation.

Mr. Keetley would remove the appendix in as large a proportion as possible, and it might be done without much risk by using gauze packing systematically, and raising the pelvis to keep away the intestines.

Mr. Charles Symonds supported Mr. Barling in not removing the appendix in most cases. He favored immediate operation.

Sir. T. Smith urged a very low incision. If pus did not appear, he then put in a drainage tube and after a time the pus would work through it.

Dr. Caley had collected statistics, which showed the mortality was not more than 1.5 to 2. per cent.

At the Medical Chirurgical Society, Mr. C. Heath related two cases of ligature of the left carotid for aneurysm of the arch of the aorta.

Mr. Heath has operated on seven cases, and those related are the two last, and in both there seems to have been benefit. In the sixth case, in a woman sixty-one years old, the left carotid was tied without an anæsthetic, on November 16, 1890, and on the 19th the respiration was no longer noisy, and she was able to recline against her pillows; on the 21st she slept for seven consecutive hours. She progressed favorably and lived more than a year after the operation, and eventually died suddenly. The other patient was a man, thirty-six years old, and his left carotid was tied under eucain B. on January 18, 1899. Improvement was noted daily until February 1, when he was free from pain and had slept well since the 20th. On February 16 his temperaure rose to 103, and he rapidly developed acute phthisis and died on March 21. Mr. Heath exhibited the specimen and three others. He held that ligature of the left carotid undoubtedly produced an immediate affect on aneurysm of the arch, and thought the sudden deaths which occasionally occurred some months later might be due to the ultimate solidification of the aneurysm partly through pressure and partly to the induction of syncope.

Dr. Frederick Roberts, under whose care the second case had been, said the chief indication for the operation was the extreme pain the man suffered, and that in spite of free aortic regurgitation and marked arterial degeneration. The operation was beneficial in respect to the physical conditions of the aneurysm, as well as to the patient's sensations.

Mr. Carless mentioned a case in which the left carotid was tied, and twenty-four days later the subclavian. Six months later there was but little pulsation felt above the clavicles, and the patient, a woman forty years old, went about her work with comfort for three years, and then died suddenly from rupture of the aneurysm into the left pleural cavity.

Mr. Barwell said in some cases it was better to tie the vessels on the right, rather than the left side, and Mr. Heath, in his reply, admitted that this was so.

The Gynæcological Society pursues its course with the vigor of youth, in spite of the supercilious disparagement of its older sister. The inaugural address of the president, Dr. Halliday Croom, on the 13th inst., was a very interesting one, particularly in reference to surgical gynæcology.

The remark that total rest cannot be given to the reproductive organs led to a summary of the process of menstruation—the very gentle passage from physiology to pathology, "almost what one might call a pathological condition occurring monthly, which we may consider a monthly miniature pregnancy—for weeks a preparation, for days an anticipation, and the hemorrhage as the tears of disappointment the uterus sheds."

But I refer to this address chiefly as to Dr. Croom's views on cancer, which he says is largely on the increase. In favorable cases of uterine cancer, he has published his results of vaginal hysterectomy, but cannot claim that operation prolongs life, or even renders death easier. Where the disease has advanced far he thinks it best not to interfere. In dealing with cancer he recognizes the necessity of clearing out the glands, but only 40 per cent. of cases, in the mammal, offer what is termed permanent cure, and recurrence is common enough in another part after three years. But in the uterus the difficulty of dealing with glands and lymphatics meets us, and further, it is remarkable how seldom cases present themselves at an early stage. Hysterectomy for cancer, on account of these conditions, has not been a great success, and while some may be relieved it is never possible to promise a cure.

Mammary and uterine cancer are, therefore, not to be compared. The one is constantly recognized early, and statistics give a satisfactory result. The other is very different; the victims seldom seek help until all chances of relief have passed by.

Two cases of late rickets were shown at the recent clinical evening of the Medical Society, by Mr. Muirhead Little. One was a girl thirteen years old, the other a lad seventeen years old. Mr. Little had performed MacEwen's osteotomy on both patients with excellent results. He found the bones very soft and easily penetrated by the osteotome. This, apparently, was why one member suggested that the cases should be classed with osteomalacia, but as there was enlargement of the epiphyses and other signs of rickets, the suggestion was not well received.

Mr. Owen showed at the same meeting a case of traumatic rupture of the prostatic urethra in a boy of seven, who had made a remarkable recovery from that and other injuries.

Smallpox persists—forty to fifty fresh cases a day. Last night there were 1,309 cases under treatment.

Dr. Thresh, the M. O. H. for Essex is convinced that infection has spread from the hospital ships by aerial connection. The theory that smallpox is thus conveyed receives, therefore, another support.

Influenza is again epidemic here, as you have probably learned from the newspapers, for several cabinet ministers and other celebrities are down with it.

The Royal Medical and Chirurgical Society's dinner on Wednesday was a very successful one, and Dr. Conan Doyle was among the speakers.

THE CURE OF CHRONIC BRIGHT'S DISEASE BY OPERATION.

Es liebt die Welt das Strahlende zu Schwärzen,
Und das Erhabne in den Staub zu ziehn.—Schiller.

To the Editor of the Medical Record:

Sir: In your issue for December 21, 1901, Dr. Geo. M. Edebohls published a paper under the above title, which paper commences as follows: "The proposition to treat chronic Bright's disease by operation was first made by the author in a paper entitled, 'Chronic Nephritis Affecting a Movable Kidney as an Indication for Nephropexy,' published in the *Medical News* of April 22, 1899, and this latter paper of Dr. Edebohls in the *Medical News* commences as follows: 'The voluminous literature on movable kidney is practically silent upon the subject-matter indicated in the title of this paper. The few and scattered words devoted to the sentiment that in the presence of chronic nephritis nephropexy for movable kidney is to be avoided in common with all other operations not called for as a vital indication. In quite an extensive search of the literature I have been unable to find the record of a single case of nephropexy for movable kidney performed upon a patient suffering at the time of the operation from either acute or chronic nephritis.' "

From all this it appears that our distinguished colleague, Dr. Edebohls, means to say that he has been the first who discovered the effect of nephropexy on the kidney affected with Bright's disease.

As it will happen, like in the case of Schleiden and Schwann, in the year 1840, who, simultaneously, but absolutely independent from each other, discovered the cells and established the cell theory, some discoveries are made by different men independently from each other, and such is certainly the case with Dr. Edebohls' discovery, only that here several surgeons, years ahead, had already made the discovery. In his research in literature, although quite extensive, as he says, he has overlooked the *Lancet*; he has not seen an article of Reginald Harrison in this journal's issue for January 4, 1896; he has not found that the surgeons, N. Rose, Newman, and Ferguson had, in German, French and English journals respectively, established already the fact which he discovered, independent of these writers at a later date. Especially noteworthy is a case published by Rose, who performed nephrectomy in a case of movable kidney, in which case albuminary was present. Ch. Mongour quotes this case in the *Journal de Médicine de Bordeaux*, February 9, 1902, saying, "In Rose's case especially, the kidney was affected by well characterized chronic nephritis, and the urine, examined several years after the nephropexy, revealed absolutely no sign of venal lesion."

Pourson, who had searched more successfully than our colleague Edebohls, having found the records of these cases of Rose, Newman and Ferguson, had an idea to practice nephrotomy in order to remedy the grave and threatening condition of chronic nephritis, and has published his first results at the Congrès de l'Association Française d'urologié, October, 1901, and, as we read in the *Journal de Médicine de Bordeaux*, February 2, 1902, Pourson had, during the three preceding years, operated *six* kidneys affected with Bright's disease, and he demon-

[illegible] operated upon [illegible] years, had been suffering from a severe form of Bright's disease. The medical treatment had been of no avail. The operation had been performed on July 3, 1901, and the case, when brought before the Society, was considered completely cured.

[illegible] that Edebohls' operations [illegible] However, Pousson and M[illegible] communications, and [illegible] the article of Reginald Harrison in the Lancet of January 4, 1902, [illegible] evidence that Edebohls was not the first who [illegible] Bright's disease by operation. A. Rose, M.D.

Progress of Medical Science.

The Boston Medical and Surgical Journal, March [illegible]

A Clinician's Estimate of Alcohol as a Therapeutic Agent.—F. C. Shattuck holds that the healthy man under ordinary conditions in this climate does not require alcohol, although he can use it moderately and habitually for years without apparent harm. In disease, however, it is often needed, and the burden of proof rests with those who deny its value. The difference between its use as a drug and as a beverage should be kept clearly in mind. The author agrees with Osler that alcohol is, as yet, the only known agent which can counteract the gradual effect of poisons developing in the course of acute febrile diseases, such as typhoid and pneumonia. Its use in acute diseases involves small risk of the establishment of a vicious habit. In chronic diseases it may be very useful, but its administration should be carefully guarded by a realization of its dangers.

Practical Experience with Hydrotherapy.—J. J. Putnam and G. W. Fitz report the results of their experiments to determine the effect of different kinds of baths on blood pressure, pulse rate, urea excretion, etc. The classes of cases which seem to offer especially interesting fields for study are the tuberculous, the diabetic, the anemic, the neurasthenic, the rheumatic, and the cardiac. The clinical cases to which the authors refer are, first, ten of neurasthenia, the form of treatment used was the "tonic" bath, and the result was improvement in nutrition and a sense of stimulation. Seven cases of tabes obtained relief of pain, and to a certain extent, of the distressing girdle sensations. Baths and exercises combined gave good results in a case of spastic-ataxic paraplegia, one patient with neuritis received benefit, and one did not, the patients with paralysis agitans improved in so far as general nutrition and a sense of well being were concerned. The authors give details as to the temperature of the water, and the manner of applying the treatment.

Journal of the American Medical Association, March 15, 1902.

Dermatomycoses in Their Relation to Allen's Iodine Test.—J. Sobel states that for purposes of classroom demonstration, the Allen test (Lugol's solution) will serve to bring into greater prominence visible parasitic lesions and into view pale, hidden, and sometimes invisible ones. A positive reaction to Lugol's solution, in the form of a deep mahogany or dark brown discoloration, is strong presumptive evidence that the lesion is parasitic. In the absence of absolute proof of the parasitic nature it is of the greatest aid, and in the presence of a parasitic skin lesion it serves to make assurance doubly sure. It is not of service in differentiating one parasitic disease from the other, this must be accomplished by other clinical and microscopical data.

Pneumatic Differentiation in the Treatment of Organic Diseases of the Heart.—By this term C. E. Quimby refers to the use of the pneumatic cabinet. He maintains the following propositions. (*a*) Any agent which decreases vascular tension and coincidently maintains or increases nutrition throughout the entire system, and only such an agent, is an ideal therapeutic measure in organic cardiac disease. (*b*) Pneumatic differentiation lowers vascular tension, increases blood flow and coincidently increases nutrition. (*c*) It is applicable to the pathic conditions of valvular lesions. Clinical results prove the accuracy of the foregoing propositions and establish the power of this measure to neutralize the injurious effects of organic cardiac disease more quickly, fully, and permanently than can any other known agent.

The Origin of Carcinoma of the Stomach from Chronic Round Ulcer of the Stomach.—G. Fuetterer gives the histories of several personal cases, illustrated by some excellent photographs. He also reviews the literature of the topic suggested by the title, and comes to the following conclusions: (1) If a carcinoma develops from a chronic ulcer of the stomach, then this development occurs from those parts of the margin of the ulcer which are most exposed to mechanical irritation by the contents of the stomach. (2) In the pyloric region it is the lower pyloric margin of the ulcer which is most exposed to mechanical irritation, and from which carcinoma develops. But other parts of the ulcer may be the ones involved when contractions and adhesions have changed the position of the organ. (3) Development of carcinoma from ulcers of the stomach in the pyloric region occurs with great frequency, while such a development occurs less often in other parts of the stomach. (4) If what has been said under the third conclusion is correct, then we must in all cases in which an ulcer of the stomach or its scar narrows the pylorus, recommend early a gastro-enterostomy to prevent the development of carcinoma. If a gastro-enterostomy has been made, then the mechanical irritation of the ulcer in the pyloric region by food is reduced, and the severe friction necessary to produce a carcinoma will probably not occur. (5) A patient suffering from the consequences of a stenosis of the pylorus, particularly if this is caused by ulcers and scars, should, if a gastro-enterostomy is not performed, be advised to eat slowly and little at a time, and to be particularly careful about carbohydrates, and especially hard crusts of bread; they should avoid simply fried, or other coarse food, and they should, as much as possible, confine themselves to liquid or semiliquid foods. A good deal of fatty food should be recommended. (6) Elderly people in particular, who have but few or no teeth, and a saliva which is insufficient in quantity and quality, must be most carefully advised as to their diet. (7) From the fact that carcinoma does not develop from the large ulcers alone, but may be developed from the very smallest, the prognosis of ulcer of the stomach is bad. Our aim, therefore, should be to prevent the formation of ulcers, rather than to heal them after they are formed, and this may be done, at least to a certain extent, by the energetic treatment of all cases of chlorosis and secondary anemia that come under our observation.

New York Medical Journal, March 15, 1902.

Trifacial Neuralgia and Its Treatment.—H. T. Barber contributes the clinical history of a woman of eighteen years. She was given a granule containing one-tenth of a milligramme of aconitin every four hours, and after she had taken five her pains were greatly lessened. She was then given a pill containing iron sulphate and extract of anthemis. This led to a final cure. One or two relapses were similarly treated and with a like happy result. The author has seen no mention in literature of this combined mode of treatment.

Chancroid of the Eyelid.—A case of this nature is reported by M. L. Foster, whose patient was a man of thirty-six years. One month before coming under observation he had contracted a sore on the penis, followed by suppurating buboes in the groin, which up to that time had not healed. Ten days before the patient was seen a sore appeared on the edge of his right upper eyelid and had slowly grown worse. There was no history of traumatism, and the general condition of the patient was by no means enfeebled. When first seen the entire lid was red, swollen, and drooping over the eyeball. In the middle of the intermarginal space was an ulcer 6 or 7 mm. long by 2 mm. wide, its floor excavated and covered with a purulent detritus, its edges abrupt and elevated, but not indurated. The preauricular and lymphatic glands of the neck were not enlarged, and there were no symptoms of syphilis present. Frequent cleansing of the eye with a solution of corrosive sublimate, 1 to 5,000, produced immediate improvement, and the ulcer was soon healed. The patient was kept under observation and no symptoms of syphilis had appeared three months after the supposed date of his exposure and two months after coming under Foster's observation. The author refers to several previously reported cases and discusses the question of differential diagnosis.

Uric Acid; Its Sources and Effects.—James Tyson believes the drift of modern teaching to be that uric acid is solely the product of excessive leucocytosis, and that its accumulation in the blood arises from this source rather than from defective renal function. There are two main indications for treatment: (1) A reduction in nuclein catabolism, (2) A raising of the processes of oxygenation. To attain the first object everything should be avoided that will produce a leucocytosis. To this end a number of drugs, such as quinine, pilocarpine, and atropine, should never be administered, and certain articles of diet that we know produce leucocytosis—notably proteids—should be reduced. Nuclein-containing foods, such as sweet-breads and other internal organs and yolk of egg, should be avoided. Over-eating should be forbidden. Iron should be administered in the same forms and on the same rational principles as it would be to a chlorotic patient. Arsenic should, therefore, be combined with it. Whatever medicinal and hygienic measures tend to a successful æration of the blood should be employed. Accordingly, the most striking results have been obtained in acute cases by inhalations of oxygen gas. On six occasions it is claimed that gout was aborted by inhalations of oxygen repeated at short intervals. The same remedy may also be used to relieve a uric-acid headache and various lithemic attacks.

American Medicine, March 15, 1902.

Sprue in Manila: A Disease or State.—William E. Musgrave states that sprue symptoms are nearly always found in the presence of other and well-known lesions, discoverable by careful clinical studies, aided by microscopical methods. Careful studies of these cases by modern methods fail to indicate an additional etiologic factor, and with our present knowledge it is more rational to consider sprue as a state or symptom group (comparable to the typhoid state), occurring in the tropics in chronic diseases, especially those affecting the gastro-intestinal canal.

The Use of Borax and Boric Acid as Food Preservatives.—Victor Vaughan and William H. Veenboer conclude that: (1) The use of borax or boric acid as a preservative in butter and cream in the quantities specified in the recommendations of the English Commission is justified both by practical results and by scientific experimentation; (2) The dusting of the surfaces of hams and bacon which are to be transported long distances with borax or boric acid, not exceeding 1.5 per cent. of the weight of the meat, is effective, and not objectionable from a sanitary standpoint; (3) Meat thus dusted with borax or boric acid does not become slimy, because the preservative thus used prevents the growth of ærobic, peptonizing microorganisms.

Modern Treatment of Drug Habitation.—Frank R. Searles gives the different methods of treatment of drug, habit as sudden and complete withdrawal; substitution and gradual tapering off. He declares that few morphine *habitués*, especially those who have long indulged in the habit, can stand the shock of sudden withdrawal. There is danger of hallucinatory delirium and collapse, in which the patient may die. Those who use the hypodermic needle form the largest class, death being often due to an accidental overdose, as well as by weakened heart action during a too rapid withdrawal of the drug. Such treatment is too radical. In the majority of cases substitution does not give satisfaction, and seems merely a waste of time. So soon as the physical condition of the patient will allow, gradual withdrawal of the drug is the preferable method of cure, but no two patients can stand the same rapidity of reduction. In some cases cutting the dose down one-eighth or one-fourth each day results admirably; in others, a lessening of one-sixteenth is as much as can be effected without signs of depression.

Medical News, March 15, 1902.

The Rate of Growth of Epithelium of Ulcers; Observation of 100 Cases at the Vanderbilt Clinic, New York.—Sigmund Deutsch, as a result of his observations, gives the following summary: The rate of the growth of epithelium is in direct proportion to the size of the ulcer; in the majority of cases the average growth of epithelium is from 2 to 3½ mm. per week; the range is 1.4 to 10.5 mm. (traumatic ulcers not included); the time required to heal an ulcer is in no proportion to the duration of the ulcer; an ulcer of four months' standing does not heal quicker than one of four years' standing, other conditions being equal; the rate of growth of epithelium in traumatic ulcers is extremely irregular; it is in no relation to the size or duration of the ulcer; the average growth per week is about 5 mm.; the range is from 1.4 to 8 mm.

Acute Influenzal Nephritis in Childhood.—B. K. Rachford believes that acute nephritis occurs not infrequently as a manifestation of influenza in children. He reports several cases which he has seen. Each of these cases occurred, not as a sequel but as a part of the influenza attack. The kidney symptoms in every case occurred while other active influenza symptoms were still present. The poison of the disease attacked the kidneys and caused a most violent acute nephritis just as it, in other cases, attacks and causes inflammation of the meninges, the lungs, the intestines and other parts of the body. Acute influenzal nephritis, as seen in these cases, makes its appearance more quickly and violently than nephritis caused by scarlatina, diphtheria, and the other acute infections. The writer believes the worst symptoms in these cases to appear generally within six or seven days after the kidney is attacked. If complete suppression and profound uremia do not cause death within the first week, a sure and steady improvement begins which results in recovery. The writer has never seen a case of chronic nephritis result. All of these remarks apply only to influenzal nephritis as occurring in infants and young children, as in adults the picture is very different. From his own experience, the writer believes the acute influenzal nephritis of childhood not a sequel or a complication, but a part, of the influenza attack.

Philadelphia Medical Journal, March 15, 1902.

Cerebral Apoplexy.—Edward D. Fisher, in considering the treatment of cerebral apoplexy, advises in regard to ordinary attacks, outside of speedy movement of the bowels by enemata, calomel or croton oil, absolute rest; and unless there is collapse, no administration of drugs. If the pulse is full and bounding, bleed through the veins, *i. e.* give aconite, but never use the lancet. If there is evidence of collapse with feeble pulse, give digitalis, or even whiskey and strychnine. These latter cases are usually due to thrombosis or embolus. The writer advises doing little, but giving absolute rest, and meeting the various emergencies as they arise. The most important time for treatment is in the prodromal stage.

The Report of a Case of Obliterative Pericarditis with Hepatic Enlargement and Ascites.—From the study of his own case and of the literature on this subject, Edward W. Becker believes that: (1) Pseudo-cirrhosis of the liver, due to pericardial adhesions, is a distinct entity; (2) In all cases of this condition at autopsy the pericardial sac has been found obliterated; (3) Autopsies have shown, in all recorded cases, that the ascites is due to passive congestion of the liver, causing a connective tissue formation, with subsequent contraction and obstruction of the portal circulation, the result of obliterative pericarditis; (4) In all cases of enlarged liver, with ascites without edema or enlarged spleen, a very careful examination should be made of the heart, to determine whether the symptoms are not due to chronic pericarditis; (5) The presence of ascites with enlarged liver and systolic retraction of the precordium, together with absent or later appearance of edema of ankles, is of great diagnostic value in determining the presence of chronic pericarditis.

A Study of the Cases of Accidental X-Ray Burns Hitherto Recorded.—E. A. Codman presents the following conclusions: (1) The frequency of *x*-ray injuries has been much exaggerated by the medical press, owing to the wide publicity given to many early cases; (2) The writer has been able to collect somewhat less than 200 cases, less than half of which were serious, and about one-third of which occurred in *x*-ray workers; (3) Judging from the experience with these injuries in Boston, it is the writer's opinion that a fair proportion of the severe burns are included in this series, while the dermatitis of skiagraphers is less well represented; (4) At a maximum estimate it is safe to say that not one patient in a thousand has been injured in the past five years by an *x*-ray examination, and in the past year not one in ten thousand; (5) More than two-thirds of these injuries occurred in the first two years of the use of the *x*-ray. Only one mild case is reported as occurring in the current year, those cases in which the exposure has been made for therapeutic purposes being excluded; (6) The cause of *x*-ray injuries is not definitely known. It is some form of energy closely allied to the photographically active *x*-ray, and radiates with it from the platinum terminal; (7) The primary injury is to the nerves controlling the nutrition of the skin; (8) There is no good evidence of injury to the deeper tissues without primary interference with skin; (9) The important factors which contribute to the production of *x*-ray burns are: the intensity of the current used to stimulate the tube; the quality of the tube, the distance and time of exposure and the idiosyncrasy of the patient; (10) The static machine is somewhat less likely to produce injury than other forms of apparatus; (11) From the data of the reported cases we can say that no burn has been produced by an exposure equal to or less than the equivalent of five minutes at ten inches; (12) It is impossible, from the data, to say how intense an exposure must be to produce a burn, for a comparison of the cases shows that an inconstant factor or factors exist; (13) These inconstant factors are more likely to lie in the complex human organism than in the less complicated construction of the tube; (14) General experience has shown that soft tubes produce a more intense effect on the tissues than hard; (15) While we cannot control these inconstant factors, therapeutic exposures will continue to be dangerous, and it is, therefore, important to record the exact conditions of the patient's local and constitutional idiosyncrasies, as well as those of the tube; (16) In cases of injury, the time before the appearance of the first symptom has varied from a few minutes to three weeks. Five cases have remained latent for over three weeks; two of these for five [illegible] (17) It is impossible to predict the severity of the attack from the time of the appearance [illegible] (18). The [illegible] at the [illegible] from [illegible] between the [illegible] within three [illegible] after the [illegible] the next four days [illegible] half [illegible] the sixth day. (20) In the [illegible] x-ray [illegible] the [illegible] take the entire responsibility [illegible] for [illegible] the patient [illegible] responsibility.

The Lancet, March 8, 1902

Electric Shocks.—The nature of electric shocks is fully discussed by J. B. [illegible], who says that we are quite in the dark as to definite knowledge of what happens to a human body when death is caused by electricity. The author notes that an idiot does not seem to feel a shock so severely as does an ordinary person. Also the shock is less felt if occurring to a sleeping person, and he thinks it possible that electricity may act as an anesthetic like chloroform. He therefore inquires whether it would not be a proper treatment in a case of shock, before applying artificial respiration, to hold the body for a few seconds, head downwards, at an angle of 45°, thus flushing the brain and stimulating its action.

Latent Vaccinia.—J. W. Washbourn reports the case of a child with uncomplicated scarlet fever without unusual features. The child had been vaccinated two years previously in four places, only one of which took and that very slightly. With the onset of the fever the old vaccination spots seemed to take on life, and in a few days presented all the features of a fresh vaccination at the seventh day. Examination of the patient revealed very slight impetigo of the scalp, and the skin was clear elsewhere. The appearance of the marks on the arm and their arrangement were quite unlike anything in the way of secondary infection from impetigo. There was no doubt that the child was suffering from scarlet fever, and the only explanation given was that the vaccination had remained latent during two years and had started afresh with the onset of scarlet fever.

A Contribution to the Study of Intestinal Sand.—A case of this rare affection is reported by Dyce Duckworth and A. E. Garrod. The condition is to be differentiated from enteric lithiasis, which is not uncommon. The patient was a woman of thirty-three years, with a family history of gout and liability to bowel disorders. She suffered from diarrhea, and sand was found in the stools, each stool containing about a teaspoonful of it, and there being two or three loose motions each day. The sand resembled fine sand to the naked eye. Its composition was water, 12.40; organic material, 26.29; and inorganic material, 61.31. The latter contained calcium, phosphorus, and carbon, with traces of iron and magnesium. The authors believe that the sand was formed in the bowel and had no biliary origin. Such sand is usually met with in cases of muco-membranous colitis. It is believed that the upper part of the colon is the special seat of formation, as this is the region in which the conversion of bile pigment into urobilin is already far advanced, and the richness of the material in urobilin and its poverty in unaltered bile pigment suggest formation in such a region.

Some Experiments to Determine the Actual Efficacy of Izal Oil as an Intestinal Disinfectant.—M. H. Gordon believes that izal oil diminishes greatly the number of bacteria in the bowel, and that, too, without untoward effect. The number of bacteria remaining in the feces is still large, but the author cannot regard this as a reason for withholding the remedy in those cases in which it is indicated. In a given case, he says, the diminution effected may make a great deal of difference to the progress of a given case. Again, for aught we at present know to the contrary, the health of the intestine may be dependent on a state of equilibrium of its bacterial contents, and a slight disturbance of this equilibrium may be a [illegible] resulting in serious illness. The indication in such a condition would be to restore the disturbed equilibrium, and a drug that can be depended on to achieve this result with certainty and without injury, pain, or other untoward result, is one to be highly valued. Theoretically it is probable that by pushing the dose of izal, but still keeping outside the limit of its toxicity, the number of fecal organisms may be still further reduced. Again, by combination of izal with other drugs and by careful dietetic treatment it may be possible to reduce still further the pathogenicity and foulness of the intestinal contents.

A Case of Reduplicated Cardiac Impulse and Heart Sounds.—J. M. [illegible] examined a man who was in apparently perfect health and free from any cardiac symptoms. There was a double cardiac impulse of regular occurrence in the normal position, the second slighter impulse immediately following on the heels of the first. There was no increase of precordial dulness. There was a slight [illegible] of the first sound in the aortic area, and the sounds, like the impulse, were reduplicated. There was [illegible] at the apex, the second group being like an echo of the first or louder sounds. There was, however, no reduplication of the pulse. The complete absence of any cardiac symptoms, the lack of cardiac hypertrophy or dilatation of the heart, and the unfailing regularity of the second impulse did not suggest the missed beat of a [illegible] organ. The [illegible] tracings showed the first systole filling the great bloodvessels and causing the pulse wave and first strong cardiac impulse. The apex remaining all the time in systole, there then occurred a second contraction of muscular fibers principally or alone at the base of the ventricles. The great bloodvessels were not dilated by this contraction, but it doubtless gave rise to the second cardiac impulse and to the fainter, echo-like heart sounds. This peculiar condition of secondary [illegible] contraction was due no doubt to some irregular innervation of the cardiac muscle and was not of the nature of the missed beat of a failing organ.

The Results of Operation in Sixty Cases of Malignant Disease of the Breast.—Marmaduke Sheild gives an abstract of the histories of the cases and some remarks upon his own operative methods. He comes to the following conclusions: (1) That the risk of removing cancer of the mamma by extensive operation is small and should not amount to more than 1 or 2 per cent. Sepsis is preventable, and when it occurs it is a blameworthy error on the part of the surgeon. (2) That early and free removal gives prospect of years of freedom, and in a good percentage of cases, of good health and enjoyment of life. (3) That the cases which do badly are (a) soft, rapidly growing cancer in young and vascular women, and (b) cases of long continuance before operation, where the skin and cervical glands are widely infected. (4) That in certain cases visceral cancers and cancers in the liver coexist with or rapidly follow operation, and the explanation of these is uncertain. (5) That the practice of early exploration by incision of small nodules and indurations in the breast is of the first importance, and should be strongly urged upon the profession generally, especially upon those in general practice who so often see these cases in their early beginnings and upon whom the great responsibility of prompt diagnosis falls. (6) No one should undertake an operation for mammary cancer unless he is capable, and has had sufficient operative experience, to remove thoroughly all lymphoid tissues from the axilla, the leaving of infected glands toward the apices of the axillary spaces being a common source of failure in the results of this operation. (7) The prognosis of mammary cancer is still dubious, and one meets instances which falsify ordinary experience. Bad cases have long freedom from return. Early cases show recurrence. But such do not invalidate the rule. Operate early, operate extensively.

The British Medical Journal, March 8, 1902

The Influence of Phosphorus on Organic Substances in Pills.—W. Harrison Martindale, for the purpose of examination, had phosphorus pills prepared, with the addition of strychnine (base), [illegible] (base), quinine sulphate, nitroglycerine, and zinc valerianate, respectively. He satisfied himself as to the absence of any considerable interaction or decomposition in the case of alkaloids. He found, on further examination, that in the case of the phosphoretted suet mass, pills composed of reduced iron in various combinations with strychnine, quinine, etc., in which one might expect to find decomposition, would show a luminous surface on cutting even twelve months after they had been prepared. This is a good proof of the protective action which the fatty base exerts. The indication, in general, is that no great amount of oxidation of the phosphorus had set in at the last examination of the pills. Of the combinations of nitroglycerine by far the best in their result were those prepared with simple theobroma oil solution. In the case of the zinc valerianate there was evidence of a combination, but this had probably taken place in the process of extraction.

A Case of Tumor of the Cerebral Cortex.—H. Cecil Barlow reports the findings at autopsy in the case of a man aged fifty-seven years, who, although apparently in good health, was suddenly seized with convulsions, which were confined to the left side of the body, mainly affecting the face, but also the arm. On examination he was found to be perfectly conscious, but unable to articulate distinctly. There was frequent and marked spasm of the left facial muscles, of the left arm, and to a less extent of the left leg. The mouth was open, the tongue protruded, and saliva flowed from the mouth. The deep reflexes were very brisk on the affected side, while sensation was markedly dulled and delayed to pain and touch on that side. The pulse-rate was 78. He appeared free from pain. About two weeks after this he died suddenly without any preliminary coma, apparently from heart failure. At autopsy there was no abnormal appearance of the dura mater and no marked increase of tension. There was marked injection of the vessels of the pia arachnoid over the right Rolandic area. Just below the surface of the cortex, which was considerably softened for a distance half an inch round it, was a perfectly circumscribed firm tumor, the size and shape of a walnut. The main bulk of the tumor was situated in the lower part of the ascending frontal lobe. It was an alveolar sarcoma.

Puerperal Insanity.—Robert Jones, in referring to the cases from which he has taken statistics, states that out of the 3,500 admissions to institutions, 259 were admitted suffering from insanity, for which reason pregnancy, confinement, the puerperal state, or lactation were assigned as a cause, a proportion of 7.4 per cent. These were classified as follows: Fifty-six were from pregnancy, a proportion of 21.62 per cent.; 120 occurred during the puerperal period, a proportion of 46.33 per cent., and eighty-three were associated with lactation, a proportion of 32.43 per cent. The very great changes comprised in gestation, the nervous excitation, the introspective life, etc., must produce many actions and reactions which may give rise to morbid mental action resulting in insanity. This is the case more especially in the single, where shame is an additional strain. The insanity is of a more unfavorable turn in single women. Of the puerperal cases, more suffered from mania than melancholia, and more from the acute form of mania than from the similar form of melancholia. Of the lactational cases, a greater proportion suffered from the depressed than from the exalted form of insanity. The onset in the puerperal cases was more often sudden than gradual, and the gradual onset characterized the advent of melancholia twice as often as mania. The symptoms of puerperal mania in 40 per cent. occurred within the first two weeks, and of these more than one-third occurred within the first week. Nearly 50 per cent. had some hereditary predisposition, either physical or mental. The greatest number of cases of insanity of pregnancy and of the puerperal period occurred between the ages of twenty-five and twenty-nine years, whereas the greatest incidence in lactation cases was between thirty and thirty-four years. This supports the view that this latter form is closely related to exhaustion. Of the 120 puerperal cases, 48 per cent. were described as cheerful, 15 per cent. as reserved. Of the lactation cases, 42 per cent. were cheerful, and 18 per cent. reserved. Most had brown hair and brown or gray eyes. Very few had dark hair, only two had red hair. Several had fair hair.

Deutsche medicinische Wochenschrift, February 20, 1902.

Nephralgia, Nephritic Hematuria and Nephritis.—H. Senator writes in opposition to Israel's opinion that nephralgia and nephritic hematuria can be produced by excessive congestion of the kidneys. Israel's idea is that such a congestion produces marked increased tension, which, in turn, causes the symptoms. Senator discusses in detail the postulates laid down by Israel and the cases reported by him, in which incision of the kidney was performed for a relief of the symptoms. He shows that in reality only two of these fourteen cases showed increased tension of this organ, and that the improvement obtained could thus not be reasonably ascribed to a lessening of such tension by incision. Furthermore, the observations which go to show that nephralgia and nephritic hematuria can be caused merely by increased tension without the presence of anatomical lesions are insufficient,. Many of the cases so reported have been submitted only to microscopic post-mortem examination. Even in those cases in which sections of the kidney were examined microscopically such examination has not been sufficiently extensive, and only a small portion of the organ has been thus examined. In these cases, therefore, it cannot be said with anything like certainty that no anatomical lesions of the kidney were present. In all the cases of nephritic hematuria which Senator has had the opportunity of examining post-mortem, anatomical lesions were present. So far as nephralgia is concerned, the author believes that this is caused by adhesions of the kidney. A careful examination of most of Israel's reported cases show that adhesions of this organ were present. Senator thinks that the good results obtained by him were due to a breaking down of these adhesions incident to his other operative procedures.

Tetanus Bacilli in Gelatine.—Ernst Levy and Hugo Bruns have instituted a series of experiments in order to ascertain whether the gelatine commonly offered for sale contains, in a fair number of instances, tetanus bacilli or spores. The subject is of importance in consideration of the number of cases of tetanus which have recently been reported following the subcutaneous inoculations of gelatine for hemostatic purposes. The results obtained are surprising in that they were able to demonstrate the presence of tetanus bacilli or spores in four out of the six specimens of gelatine examined. Their method consisted in dissolving 2 to 3 gm. of the gelatine in 100 c.c. of bouillon. This was then incubated from eight to ten days. At the expiration of this time the culture was filtered through a Pasteur-Chamberlain filter, and the filtrate thus obtained inoculated subcutaneously into mice and guinea pigs. According as such animals developed tetanus or failed so to do, the test was considered positive or negative. In addition to tetanus bacilli, other spore-forming microorganisms were also found. Most authors regard sterilization by steam at 100° C. for eight minutes as sufficient to kill tetanus spores. Levy and Bruns, however, as the result of their researches, do not regard this as sufficient in all cases. It seems highly probable that identical races of tetanus bacilli may give rise to spores of different resisting power. It is certain that more work is necessary in order to definitely establish the thermal deathpoint of tetanus spores when subjected to steam. In our present knowledge, the most important point in the sterilization of gelatine is to be sure that all portions of the gelatine are equally submitted to the 100° C., and are retained at this temperature for eight minutes, counting from the time that the given temperature is reached. It has not as yet been decided whether or not such sterilization injures the hemostatic properties of the gelatine. According to J. Forster, such is the case. This question cannot be fully decided until it shall have been definitely determined upon what the hemostatic power of this substance depends.

Practical Application of the Agglutination Reaction of the Bacillus Tuberculosis.—E. Rumpf and L. Guinard consider the practical value of the agglutination reaction of the tubercle bacillus from both diagnostic and prognostic standpoints. They maintain that it is of diagnostic value and, in so far as this, disagree with the opinion of Koch. Their investigations, however, do not include tests for the presence of the reaction in healthy individuals. They examined the agglutinating power of the blood in 107 phthisical patients, of which 29 were in the first, 41 in the second, and 37 in the third stage of the disease. They obtained a positive reaction in 84 per cent. of these cases. Seventeen showed a reaction in a 1 to 5 dilution, and seventy-three in a 1 to 10 dilution. In all cases the diagnosis of tuberculosis was made as the result of physical examination or by the finding of tubercle bacilli in the sputum. From a prognostic standpoint they confirm Koch's view that the intensity of the reaction corresponds to the degree of immunity present, and increases as the general and local condition of the patient becomes improved. Their observations were made upon sanatorium patients. In such the general condition is nearly always markedly improved shortly following reception into the institution, and when such is the case examination shows that the intensity of the reaction increases therewith. In those cases which showed a reaction upon reception, but in which the general state rapidly deteriorated rather than improved, observation showed that coincident with the decline the agglutinating power of the blood decidedly decreased or wholly vanished. Acute and rapidly fatal cases and those which show healed tubercular areas, as a rule, give a negative reaction. The authors think that in the latter instances this is due to the fact that the body has been successful in its fight against the disease. An endeavor was also made to increase the intensity of the agglutinating power of the blood by the subcutaneous inoculation of Koch's new tuberculin (bacilli emulsion). In this they were successful. By repeated inoculations they frequently obtained reactions in a 1 to 20, 30, or 50 dilution when it had previously only been present in a 1 to 5 or 10 dilution. Coincident with this increase there was a pronounced improvement in the general condition. If the inoculations were at any time discontinued, the intensity of the reaction decreased and the general condition retrograded. These results were obtained by the inoculation of relatively small doses of the tuberculin (.0025, .005, and .01). In no case was there produced any unfavorable symptoms as the result of such inoculations. For the technic of the agglutination tests they employed both the methods of Arloing-Cournnout and Koch. They find that the results obtained were practically the same in both, with the exception that Koch's technic gave the highest figures in those cases which were submitted to tuberculin inoculations. However, the Arloing-Cournnout method has the advantage that in doubtful cases the microscope can be used to observe the process. With Koch's technic this is not possible, on account of the [illegible] bacilli in his [illegible]. The general [illegible] of the [illegible] itself is also the same [illegible].

[illegible]

Curettage of the Ethmoidal Sinus in the Treatment of Recurrent Nasal Polypi.—A. A. G. Guye reports four cases of recurrent nasal polypi which were removed, and the ethmoidal sinus curetted. In this manner a permanent cure was effected in each case. This method was originally recommended by Bosse and Zuckerkandl, but was subsequently condemned by Hyrtl, and has of recent years fallen into disrepute as very difficult of execution. Guye finds the technique of the curettage simple. He uses a small curette, which is introduced into the sinus through the anterior nares. After the curetting he packs the sinus with an iodoform-gauze tampon. Cocaine is used as a local anesthetic. The operation is repeated twice weekly if necessary. The first case reported by Guye was of long standing, and the growth of the polypi was dependent upon a chronic catarrhal inflammation of the ethmoidal sinus. Intense headache was a prominent symptom, and for this reason the case had been previously considered syphilitic. After thoroughly curetting the ethmoidal sinus, however, the polypi did not recur, and the head symptoms disappeared. In the second case the original polypoid growths were due to empyema of the antrum of Highmore. In spite of the fact that this was successfully treated the polypi reappeared in about three years. This time the seat of the trouble was found in the ethmoidal sinus. Headache was a prominent symptom, as in the first case. The same treatment was effective in permanently curing the condition. In the third case the ethmoidal sinus was also involved, but no headache was present. The fourth case was one of asthma produced by nasal polypi. On account of the persistence of the symptoms after removal of the polypi, the presence of phthisis had been suspected. Upon recurrence of the polypi they were removed and the ethmoidal sinus curetted. The asthmatic symptoms disappeared.

Dublin Journal of Medical Science, March, 1902.

The Diagnosis of Scarlet Fever.—J. Marshall Day says that the chief symptoms of scarlatina are vomiting, sore throat, fever, rapid pulse, and rash. Concerning these individual symptoms he lays down the following rules: (1) Actual vomiting, or a distinct feeling of nausea, is nearly always present. (2) Children so seldom complain of sore throat that unless one follows the golden rule of always looking at the throat when examining a child, this symptom may be overlooked. One may find in severe cases that the patient swallows quite well, but the converse also holds good. In mild cases there is often a peculiar dull yellowish whiteness of the hard palate on the second day. (3) At the commencement the temperature varies from 100° to 104°. It falls the next day, rising again in the evening, but not so high, and, following this course, generally becomes normal on the eighth to the tenth day. In mild cases it may become normal on the third day. (4) The pulse rate is more characteristic than the temperature, as even in the mildest cases it is over 120, generally 140 to 160, and we find that even after the temperature becomes normal the pulse rate remains higher than normal. (5) The rash in scarlatina is never seen on the end of the nose, or around the lips—i. e., in the circumoral zone. It is almost invariably out before the third day. In the very mild cases there exists a fine punctiform rash on the tonsils, the hard and soft palates, and over the surface of the body where the skin is softest, such as the flexor aspect of the arms, the sides of the chest, the lowest part of the abdomen, the upper part of the thighs, and in the axilla. It can also be seen on the backs of the hands, the sides of the fingers, and on the dorsal aspect of the feet. When the elbow is flexed a browning along the folds of the skin is noted, and a similar condition is observed at Poupart's ligament, and also, but not so frequently, at the backs of the knees. This browning persists after the rash fades, and is present with red puncta on the lower limbs. He adds that we should never attempt to diagnosticate the disease from the character of a rash without seeing the whole of it; never attempt to make a diagnosis by artificial light, and, when in doubt, always act as if the more important disease were present until its absence be certain.

French Journals.

Effects of Decapsulation of the Kidney.—Claude and Balthazard propose to substitute for nephrotomy, which has been practised in recent times in surgical affections of the kidney and grave nephritis, decapsulation of the kidney. Urinary accidents in this way will be avoided. Besides, this intervention will facilitate the reestablishment of the renal circulation in cases where the vessels are compressed by the edematous renal parenchyma and bound down by the capsule, and also in cases of arterial sclerosis. In normal cases decapsulation has not caused any notable modifications in elimination, or in purifying the body.—*Le [illegible] Médical*, March 1, 1902.

Comparison of the Effects of Chloroform and Ether.—Poncet states that, according to his own experience, chloroform is more dangerous than ether. In 25,000 etherizations he reports one death. This occurred in a child who was found at autopsy to have old cardiac lesions. Ether does not cause the primary syncope or laryngeal reflex, so suddenly fatal and relatively frequent in the use of chloroform. Simple etherization, that is, the use of plain ether, is preferable to a mixed anesthetic. Pulmonary accidents are probably as frequent in patients who have been operated on without anesthesia as in those who have been anesthetized. The contraindications remain the same as they were in the past.—*Gazette des Hôpitaux, Civils et Militaires*, March 6, 1902.

The Clinical Value of Cytology, Cryoscopia, and Hematolysis in Certain Surgical Exudations of Serum.—Charles Julliard concludes that a cytological examination of serous exudations often gives useful clinical data. The different degrees of intensity of the morbid process appear to be characterized progressively by (1) Endothelium, (2) Lymphocytes, (3) Polynuclear cells. The first are found in exudates resulting from purely mechanical causes, as chronic hydrocele, certain forms of tuberculous arthritis, etc., the second in exudates of an infectious nature, and the third in those of an acute nature. Cryoscopia is not of especial value in the diagnosis or the prognosis of the affection, neither does hematolysis give indications of practical importance.—*Revue de Chirurgie*, February [illegible], 1902.

Pathogenic Unity of Dysentery, the Specific Nature of Its Germ and the Serotherapeutic Indications.—Th. Marcel and M. Roux, from their experimental researches, conclude that dysentery, whether *nostras* or tropical, endemic or epidemic, grave or benign, is due to a specific bacillus. It is differentiated from other coli bacilli by its failure to produce indol at the expense of albuminoid material, by specific phenomena of agglutination, and by the secretion of special toxins and antitoxins. The authors are experimenting with a serum obtained by the prolonged immunization of a horse. Its properties are nontoxicity, and a bactericidal and antitoxic effect on the bacillus of dysentery and its poison. Further clinical researches are necessary before any definite statement can be made in regard to its value.—*Revue de Médecine*, February 10, 1902.

The Proper Method of Proceeding in the Case of a Doubtful Ulcerous Neoplasm of the Tongue or Buccal Cavity.—E. Lenglet concludes that: Excision of a bit of the lesion, followed by microscopical examination, is the surest, the most rapid and the least troublesome method for determining the nature of doubtful neoplastic ulcerations of the mouth and of the tongue. It allows the institution of rational treatment in each variety of these lesions. When this method cannot be followed, there is recourse to the injection of calomel, knowing that it may ameliorate epitheliomata and diminish connective tissue infiltration, but it must be remembered that valuable time may be lost in this way, as more time may be consumed than is strictly necessary for the confirmation of the diagnosis. Iodide of potassium should never be employed in doubtful cases, since it is so harmful in cases of epitheliomata.—*La Presse Médicale*, March 5, 1902.

Subcutaneous or Intra-Muscular Injections of the Yolk of Egg in the Treatment of Tuberculosis.—Ch. Bayle has had excellent results in ameliorating the general condition of tuberculous patients by giving them injections of the yolk of egg. The average weight of one yolk is 20 gr. Among the constituents of the yolk of egg are vitellin, olein, lecithin, free fatty acids, cholesterin, mineral salts, a compound of phosphorus, and water. The writer attributes a particular importance to the lecithin. In these experiments two injections a week have been made. A needle with rather a large, or at least a medium caliber, is used. It is attached directly to the syringe without a rubber tube. The egg itself is considered sufficiently aseptic. The arm and the leg have both been chosen as points for the injections. The writer is intending to use a mixture of equal quantities of the yolk and sterilized salt solution, which will increase the fluidity of the liquid, will favor absorption, and allow the injection of a larger quantity of the active material. About four cubic cm. are injected at a time. The process is carried on with great gentleness. The writer has had no case of abscess. These injections are considered one of the best methods of causing the absorption of a quantity of lecithin which has not undergone any alteration.—*Lyon Médical*, February 23, 1902.

Clinical Department.

HYPEREMESIS GRAVIDARUM.

By ENRICO CASTELLI, M.D., L.M.,
ROTUNDA HOSPITAL, DUBLIN.
WASHINGTON, D. C.

VOMITING of pregnancy is due to two principal causes: (1) To the influence of pregnancy on the central and peripheral nervous system; (2) To a process of autointoxication. In my estimation the toxic cause is the most frequent and the most easily treated.

During pregnancy there is an augmentation of the toxic products of the intestine (ptomain). The liver, that, in association with the other functions, is charged with the neutralization of these toxins, becomes, sometimes, during pregnancy unable to meet the increasing exigencies of the organism. A state of autointoxication arises, described by Pinard as hepato-toxæmia gravidica. The vomiting of pregnancy is simply one of the most serious symptoms of such intoxication.

I have been treating for two years cases of hyperemesis gravidarum on the assumption of the truth of these views. I have only nine cases in my record, but in all I had good results. My last case was in Washington a few weeks ago, and is worthy of mention. The patient, a woman aged twenty-six, lives in Mexico. She had one previous pregnancy. She always felt well. At the beginning of the third month of pregnancy (last week of October) she was attacked with vomiting. She suffered especially in the morning, but in the afternoon was as well as usual and retained her food. Her physician ordered subnitrate of bismuth. At the beginning of November she felt well, and, with the consent of her physician, started for Washington with her husband. Arriving in New Orleans, she was again seized with vomiting. This time she vomited more frequently, about ten times in the twenty-four hours, and could retain no nourishment. A physician in New Orleans prescribed bismuth and light food. The second day, the patient, thinking herself better, started from New Orleans, but was taken sick again on the train; her husband gave her the medicine brought with him from New Orleans, but she could not retain it. He endeavored to nourish her with milk and champagne, but she retained nothing. The first day of the trip she vomited nine times; the second, twenty-two; the third, thirty-seven. She arrived in Washington in the early morning of the 11th of November, and immediately sent for me. I examined the patient and found a temperature of 101°, the pulse 137; the skin was dry and muddy, mouth dry, tongue coated, breath fœtid. The small amount of urine voided was acid and had a bad odor; the eyes were sunken; she complained of headache and pains in the epigastrium; she was constipated; she had lost a great deal of flesh in the last week. She vomited, while I was attending her, water, bile, and mucus.

My treatment is causal and symptomatic. With the causal treatment I seek to diminish the toxin present in the organism and to stimulate the action of the liver. With the symptomatic treatment I seek to alleviate the vomiting until the causal treatment becomes effective.

The following was the course pursued: November 11, 1901.

8.30 A.M. First enema as follows:

℞ Aquæ	1,000 gm.
Sodii chloridi	5 gm.
Sodii sulphates	10 gm.
Veratrinæ	1 mgm.

I gave the enema through a long cannula.

10.30 A.M. Second enema of the same amount and composition.

12.30 P.M. Third enema of the same amount and composition. Each enema was followed by a discharge of fecal matter. The last discharge was watery and of a greenish color. After the third enema the patient did not complain of any pain in the epigastrium, and the headache was relieved. She vomited twice in the first two hours; three times in the second two hours; only once in the third two hours. After the third enema the patient lay on her back, head lower than the limbs, and a hot pack on the head, to be changed every twenty minutes. This was done to remove the state of cerebral anæmia always present in these conditions, and one of the exciting causes of persistent vomiting when the other causes have been eliminated.

1 P.M. Evaporization of ether on the epigastrium. After ten minutes I prescribed 6 cgm. of calomel in six powders, one to be given every half hour, followed by a tablespoonful of cold champagne and little pieces of ice.

5 P.M. The patient slept quietly for one and one-half hours.

7 P.M. I began to nourish the patient with milk and vichy water (equal parts), giving her teaspoonful doses, each teaspoonful being followed by a piece of ice. In the meantime I used the spray of ether on the epigastrium. In this way I succeeded in giving the first glass of milk which was retained.

9.30 P.M. I gave in the same way the second glass of milk, which was retained, and the patient went to sleep.

12th November, 6.45 A.M. The patient slept all night; woke up and had a movement of the bowels of watery-greenish nature.

7.30 A.M. The patient had a spell of vomiting; had no pains of any kind, no fever; the skin was moist; the tongue was clean; pulse, 90.

8 A.M. I gave to the patient a glass of milk in the same way as before; hot pack on the head. No vomiting.

10 A.M. Second glass of milk; hot pack on head. No vomiting. A glass of milk was then given every two hours until six had been taken. All were retained. One movement of the bowels, watery-greenish, occurred at 4.30 P.M. In the evening three powders of 1 cgm. each of calomel were given at half-hour intervals.

From that hour on the patient gradually returned to her regular meals, taking 3 cgm. of calomel every night. She felt well and wanted to go back to Mexico.

On 19th November she left Washington with these instructions: (1) Take milk and vichy during the trip and only one full meal in the middle of the day; (2) Take every night 3 cgm. of calomel; (3) Lie down most of the time.

On the 23d of November the patient arrived in Mexico in good condition.

The Discoverer of Serum Diagnosis.—Ronald Ross, writing upon the question of priority in the discovery of the so-called Widal test, states that Prof. Gruber gives the credit to two men who belong to England, viz., H. E. Durham and A. S. Grünbaum. He gives certain facts in detail that show pretty conclusively that the agglutinating power of the blood in typhoid disease was announced by Prof. Gruber at the Medical Congress in Wiesbaden in April, 1896, although his paper on the subject did not appear until September of the same year. The original work was done by Grünbaum in Gruber's laboratory. But before Gruber's paper appeared, Widal published several papers in the French journals claiming priority of discovery. Ross is inclined to give him the credit of priority in publication, but contends most vigorously against Widal's claim to be the discoverer of the test now commonly known by his name.—*The Lancet.*

WHAT ARE THE BEST SOLUTIONS FOR USE WITH WET DRESSINGS?

By GEORGE G. VAN SCHAICK, M.D.
NEW YORK
ATTENDING SURGEON TO THE FRENCH HOSPITAL

A wet dressing is one that is moistened with some solution which is protected from evaporation by means of an impermeable covering. For some years following the adoption of the Listerian method wet dressings were employed in the treatment of nearly all wounds, whether operative or accidental, septic or aseptic. The tendency of modern surgery is to employ the dry dressing only in cases in which the wound is presumably aseptic, since a properly absorbent covering will suffice to imbibe the normal secretions, and because the heat and moisture of the wet dressing favor the development of germs.

The moist dressing serves a limited yet most important purpose. It is to be adopted in every wound that is septic, or that is likely to become contaminated. It is necessary to appreciate as accurately as possible the factors which contribute to the undoubted usefulness of the wet dressing in such cases. Do they depend upon the presence about the wound of what has been called a moist antiseptic atmosphere, and upon contact of the solution itself with the wound, or are they simply derived from the fact that the moist dressing promotes drainage? While it is possible that both of these factors may be possessed of some value, I am persuaded through many years of careful observation that the second is of overwhelmingly the greatest importance. That the surgical world is beginning fully to appreciate this is shown by the fact that the modern tendency is to employ, for wet dressings, solutions that are constantly becoming weaker. Carbolic acid is becoming obsolete, owing to the fact that it may bring about gangrene, and that its absorption sometimes results in the production of toxic effects. Bichloride solutions are often employed in such a degree of dilution that their antiseptic effects have reached the vanishing point. Dr. Eisendrath of Chicago* mentions a Russian surgeon who in one year treated 1,500 cases of infection with ordinary salt solution, with results equal to, if not better, than those which he obtained by means of strong antiseptic solutions. The late Dr. Gibier, of this city, who constantly treated a large number of infected wounds in people who had been bitten by dogs, and who applied for the Pasteur treatment, told the writer that dressings of normal salt solutions were far more effective than any others that he has tried. Dr. Eisendrath states that in ten years he has used a 1-1000 solution of salicylic acid in about 2,000 cases with good results. In the presence of these observations it is becoming evident that surgery is gradually becoming weaned from so-called antiseptic moist dressings. The surgeon nowadays operates with clean hands upon an aseptic field, and leaves an aseptic wound covered with aseptic dressings. When dealing with an infected wound he opens every focus of sepsis that he can reach, packs deep cavities lightly with gauze, or drains them with tubes or strands of some ligature material, after which he applies a wet dressing, the chief purpose of which is to prevent all drying and caking of discharges so that the absorbent material out of which the dressing is made may continuously take up and remove from the wound all toxic substances which come to the surface. A wet dressing, therefore, acts mechanically, and it is more than questionable whether the influence of any so-called antiseptic is not an entirely negligible quantity. As a matter of fact, strong antiseptic solutions often exert deleterious effects, which are so well known that we need not stop to discuss them.

Considered as bactericidal agents, solutions of boric or salicylic acid, such as the one mentioned by Dr. Eisendrath, the ordinary Thiersch solution, and the weak bichloride solutions employed by many surgeons, possess no value whatever. Hence it might be asked whether these solutions possess any advantage at all over plain sterilized water. From the practical standpoint it is not very certain that they do. The use of the saline solution, however, is justified by the fact that it is distinctly less irritating to the tissues than plain water. The dermatologists long ago observed ill effects resulting from the continued application of plain water to the skin. A hypodermic injection of plain water is distinctly painful whereas the injection of normal salt solution under the skin causes no pain excepting that produced by the needle. We, therefore, have a distinct reason for adopting the latter for our wet dressings. Now, it is important that the dressing shall remain wet as long as possible, since, notwithstanding the impermeable covering, a certain amount of evaporation will take place. The hygroscopic virtues of the salt may assist to a slight extent in securing this object, but the employment of a small amount of glycerin will promote it a great deal. Any one who has developed photographic films knows how the addition of a small amount of glycerin to the final bath keeps the films soft and straight, which otherwise would become hard, brittle, and curly. A small amount of glycerin added to the salt solution keeps the dressing softer and more absorbent. Even without rubber or oiled silk covering, a dressing moistened with such a solution will remain moist, soft, and non-adherent to the wound nearly twice as long as one dipped in plain water or even in salt solution. The writer employs a solution composed of salt, 8 parts; glycerin, 20 parts, and water, 1,000 parts; and in nearly eighteen years of active surgical practice has never found anything which better answered his needs. From all this we may conclude that for wet dressings the ordinary antiseptics are practically valueless if considered as bactericidal agents, unless employed in such a degree of concentration as to be dangerous, and that they are best replaced by aseptic non-irritating solutions.

A CASE OF DOUBLE TONGUE.

By ALBERT SEITZ, M.D.,
McMINNVILLE, TENN.

It was my fortune recently to see a case of double tongue in the person of a boy five years of age. He is of Jewish parentage, and has always been healthy, so his father tells me. There is no other abnormality in his body so far as I could discover. He is one of six children, none of whom presents any bodily malformation save himself. He has a normal tongue, beneath which lies the rudimentary organ, which is nearly, or quite, one inch in length and a little broader than it is long. It arises where the normal tongue joins the floor of the mouth, and below the frænum of the normal tongue. The rudimentary organ is about three-eighths of an inch in thickness at its base and grows gradually thinner toward the tip. The anterior end is convex and does not come to a point, but is broader than the apex of the normal tongue. The whole of the rudimentary organ is covered with mucous membrane, and the body of it seems to be composed of muscular tissue. When the normal tongue is raised, lowered, or moved in any direction, the lower one moves with it, but does not seem to interfere at all with its functions. The boy talks with great distinctness and says his second tongue does not trouble him in any way. Neither he nor his parents knew of its existence until the night before his father brought him to my office. During the night the boy was awakened and complained of a pain in his mouth, which I think was caused by a carious tooth which I discovered on examination. His father, on looking into the boy's mouth for the cause of the pain, discovered two tongues, and was greatly alarmed, not knowing what the second organ was, and supposing it to be the cause of the pain of which the boy complained. So early the next morning he brought him to my office and I found the condition which I have attempted to describe. As the rudimentary organ was giving the patient no trouble or inconvenience I did not think it necessary to excise it, so did nothing to it, but sent the boy to a dentist to have his carious tooth attended to, as I am satisfied that was the cause of his pain. I believe Hajek and Dolaeus have each recorded a case of double tongue. This is the only case of this anomaly I have ever seen.

INTRA-PERITONEAL RUPTURE OF THE BLADDER.

By JAMES PEDERSEN, M.D.,
NEW YORK.

ASSISTANT ATTENDING SURGEON (G. U.), BELLEVUE HOSPITAL; ADJUNCT PROFESSOR OF VENEREAL AND G. U. SURGERY, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The patient was forty years old. On the evening of October 2, after some indulgence in beer, he retired with his clothes on. He arose at 3 A. M., and urinated, and soon thereafter, while sitting on the window sill removing his shoes, he fell out backward. His fall was broken by the roof of a porch a few feet below the window. The window was about twelve feet above the ground. About two hours later (5 A. M.) he regained consciousness, and was removed by ambulance to a neighboring hospital. Four hours later he was transferred to Bellevue Hospital with his left upper extremity in a splint, a fracture of the olecranon process having been made out. The Division House-Surgeon at Bellevue, while making a careful physical examination, noticed a little blood at the meatus, and suspecting rupture of the bladder, introduced a soft rubber catheter. A small quantity of bloody urine was obtained. Four ounces of boric acid solution were then instilled from an ordinary hand syringe. Only three ounces returned. Six ounces were instilled and only four returned. Again six ounces were instilled and only one and a half returned. In all seven ounces of the boric acid solution were lost. Through the courtesy of Dr. Bryant, to whose service the patient had been admitted originally, he was now transferred to the service of Dr. Bangs.

I operated an hour later, approximately, nine hours after the accident. A sound was passed into the bladder and cut down upon through the usual suprapubic incision. On reaching the peritoneum the point of the sound was found immediately beneath it. On opening the peritoneum a transverse rent in the bladder two and a half to three inches long was found just within the peritoneal reflexion. It being necessary to hasten the operation, only a continuous suture of ten-day chromatized catgut was used. It was closely applied, however, and the edges of the rent were brought together accurately. As careful a toilet as possible of the peritoneum was made; a quantity of bloody fluid and decolorized clots being wiped from the rectovesical space. The membranous urethra was then buttonholed and a 35 F. perineal tube was inserted through it into the bladder. The suprapubic incision was sutured in layers down to its lower angle, where two wicks of plain gauze, surrounded by rubber tissue, were passed to the bottom of the rectovesical space. A fold of iodoform gauze was placed anterior to these, and carried down between them and the bladder to a point just below the rent.

There was no leakage from the rent until the evening of the following day, when the drainage by way of the perineum was interrupted by some occlusion or a slipping of the tube. The fault was corrected as soon as discovered, but the leakage continued for ten days, and the fold of iodoform gauze had to be changed daily. The leakage ceased gradually. The drainage wicks were shortened from day to day; then one was removed. Thirteen days after the operation the remaining one was removed and a small drainage tube substituted, the discharge from the sinus having become purulent. Nineteen days after the operation this drainage tube was finally removed and the sinus allowed to close. The sutured portion of the wound had healed by first intention.

The penile urethra was now explored for strictures. Only a narrowing at the meatus being found, a meatotomy was performed to relieve the bladder of all unnecessary strain in voiding urine after recovery. The perineal drainage was continued until the twenty-second day after the operation. The perineal wound then healed rapidly and firmly.

The highest temperature reached was 102°, two days after the operation. From that day on it slowly declined. The highest pulse rate was 116; the respiration 36. Eight days after the operation the patient was mildly delirious and almost succeeded in getting out of bed. The temperature at this time rose to 101.2°, the pulse to 90, the respiration to 34. At no time were there physical signs of peritonitis or of pneumonia.

Both the suprapubic and the perineal wounds have remained closed. The patient urinates once in eight hours without difficulty. The urine contains only a few mucous shreds.

I am indebted to Dr. Lusk, assistant attending on Dr. Bryant's service, who kindly supervised the treatment of the fractured olecranon process.

REPORT OF AN UNUSUAL CASE OF DEAFNESS.

By DONALD M. BRISTOW, M.D.,
NEW YORK.

F. H., male, twenty-two years old, single, and a clerk, came to me at the New Amsterdam Eye and Ear Hospital on January 13, 1902. He gave the following history: He is a twin. His twin brother is living and in good health, but occasionally suffers from sore throat. The family history is negative. The patient's infancy and early childhood were uneventful. When eight years old he had an attack of acute illness, which he had been told was typhus fever. Since that time, he has had no hearing at all in his right ear. The hearing in his left ear is very good, and he has been able to get along perfectly well until lately. During the last few months he has taken up the study of choral singing, and finds himself handicapped by not being able to hear the singing on his right-hand side. This is his reason for applying for treatment. He has never noticed any temporary improvement in his right ear. He does not think it has grown any worse lately. His health is always good.

The patient is well nourished, the nose and throat show nothing abnormal. The left ear is normal in appearance, and responds normally to all tests. The right drum membrane is retracted, the short process of the malleus abnormally prominent. The drum is somewhat pale, but apparently not thick-used. The cone of light is very distinct and slightly elongated. My watch (normally heard at thirty-six inches) cannot be heard even when pressed hard against the auricle. The tuning-fork (G) is heard by air conduction, not at all; by bone conduction, twenty seconds. The Eustachian tube admits air freely, either through the catheter or by Politzer's method.

The patient's ear was subjected to an energetic inflation through the Eustachian catheter with no result. The large pressure-probe was then used, without effect. The following day the patient was subjected to pneumatic massage, after which the pressure-probe was again used and finally the ear was inflated with the catheter. Result: the watch is heard faintly on close contact and the tuning-fork by air conduction is heard for nine seconds.

During the next three weeks the patient was treated every second day by the pressure-probe, followed by catheterization. He showed slight improvement after each sitting for the first two weeks. Then he began to improve more rapidly, and on the eighteenth day from his first coming, he heard the watch four inches from the auricle. This was sufficiently encouraging, but on the twenty-first day, to my great astonishment, he heard the watch at thirty-six inches, and, with his left ear tightly plugged with cotton, he heard every word of a conversation which happened to be in progress in the next room, all of twenty feet from him. Since then (three and one-half weeks) I have had him come once a week for inflation, and his hearing has continued to improve until now he hears my watch at five feet, or about a foot further than I can hear it myself.

This case is quite unique in my experience, and I have been unable to find a similar one reported. The boy had been absolutely deaf, to all intents, on one side for fourteen years, and there had been, apparently, no active catarrhal process in operation during that time. I had, of course, given an uncertain prognosis at the outset, and had told him that if he should improve, the improvement would be very slow. My view of the pathology of the case is, that the deafness was due to simple fibrous ankylosis between the ossicles, and that the bands were stretched and, perhaps, broken, by the pressure probe.

31 West Fifty-third Street.

Orthopædics of the Ovary.—E. Rose refers to orthopædics of the ovary as those measures directed toward replacing this organ to its normal position, when it has become displaced therefrom. He reports two cases where such measures were undertaken and followed by successful results. In the first case, the patient presented herself with a tumor in the region of the external abdominal ring, which was tender upon pressure and not movable. Upon cutting down the ovary was met with. Since this was not diseased, it was returned to the abdomen and the wound closed. No further discomfort was experienced by the patient. The second patient had long complained of abdominal pains and had previously had the right ovary removed. Following this, however, the pains returned, although they were largely intermittent in character. Upon examination on the left side, coinciding nearly with the course of the left ureter, there was detected a long indurated swelling about the size of the index finger at the lower extremity of which there was a small oval tumor. A diagnosis was made of stone in the ureter. Upon operation the ureter was found to be normal, but the anterior border of the psoas magnus was seen to be thickened and very prominent, and the left ovary was lying upon this muscle bound down by the peritoneum. This organ was freed and returned to its normal position. Complete recovery followed.—*Deutsche Zeitschrift für Chirurgie.*

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 24, 1902.

Frank Van Fleet, M.D., President.

Psychopathic Epidemics.—Dr. John B. Huber presented this paper. He said that at the present time there were several movements which seriously affected our national life, and all of them appeared to him to be of the nature of psychopathic epidemics. They all present certain common characteristics. Each cult asserted that theirs alone is the storehouse of truth, and that all others should be thrown aside. An abnormally-minded individual was capable of influencing his followers to matters less [illegible] than supernatural powers. As examples, the speaker referred to the present movement of the Christian Scientists and the brilliant but short-lived career of Mormon. The movement of Sanford culminating in the erection of the magnificent temple at Shiloh, and the sudden disappearance of Sanford, was described. Some of the grotesque doings at the meetings led by the Rev. A. B. Simpson were narrated, and that gentleman was quoted as having said at the close of a meeting at which eight thousand dollars had been subscribed, "What the Lord can do with simple-minded people is marvelous." Dr. Huber went on to say that it was with a feeling of regret and sympathy that he sketched the character and history of Schlatter, a poor shoemaker, whose doings were characterized by a rude sincerity. He did not think that Schlatter was consciously an impostor; he was undoubtedly insane. That there was nothing miraculous about his so-called healing powers was patent to every medical man, but the influence he exerted was certainly most pernicious. Osteopathy next received the author's attention. He said that all diseases were claimed to be due to the dislocation of some bone. Some vertebra was usually the culprit, and was subjected to a prolonged course of massage. Dr. Huber said that some time ago he had examined a series of cases claimed by the leaders of the Christian Scientists to be cures, and had been impressed chiefly with the great disproportion between the results claimed and those which he had observed. The most potent influence in swelling the ranks of these various cults was the faculty of imitation, always so prominent an element in a large popular movement.

Melancholia Simplex.—Dr. Ralph Lyman Parsons was the author of this paper. (See page 406.)

Dr. S. A. Knopf read several quotations from Mrs. Eddy's book on Christian Science. Mrs. Stetson, referring to this book, said: "That book, I believe, can cure anybody who reads it understandingly, of any disease, even of consumption." On page 388 of this book are found the words, "The less we know or think about hygiene, the less we are disposed to sickness." Dr. Knopf added that in this teaching lay the greatest danger of Christian Science. He incidentally called attention to the fact that the Christian Scientists had never invaded the haunts of the poor or endeavored to heal their less fortunate brethren. They insisted that, in order to have the necessary faith, payment should be made in advance, and as the poor could not do this they did not come under the kindly influence of Christian Science.

Dr. Theodore Kellogg said he was disappointed that the first paper had not brought out more forcibly the psychopathic influences involved in the many "isms" described. Peculiarities of religious belief and practice were not, in his opinion, truly psychopathic. Since the world began there had been an almost endless number of religious beliefs. The paper on melancholia simplex was very practical and well founded on clinical facts, but the all-important problem of diagnosis was still left somewhat obscure. Attention might well be directed to the defects of nutrition, the insomnia, the characteristic peculiarities of the pulse, the increased arterial pressure, the subnormal temperature and the various perverted functions of the body. Melancholia, in his opinion, was chiefly a physical disorder, the mental affection being really a reflex of the physical state. In the slight and transitory cases it was almost impossible to make the diagnosis. The physician assumed a very grave responsibility when he publicly made the diagnosis of melancholia and insanity, and hence it was well that the physician often recognized it quietly, but avoided speaking of it or acting in such a way as to attach unnecessarily a stigma to the unfortunate person. For this reason he was not disposed to agree with the writer of the paper as to the advisability of sending such patients even to a private hospital.

Dr. **Robert T. Morris** said that our legislators should be made to understand the nature of these psychopathic epidemics, in order that they might not place too much weight upon the claims and arguments of the victims of these epidemics. We should also collect specific instances of injury to present to our legislators.

With regard to the second paper, he would like to lay more emphasis upon the influence of organic disease upon melancholia. Surgeons were in the way of seeing melancholia and other more marked examples of mental derangement that were relieved by surgical means. Loose kidney and diseased uterine appendages were responsible for a certain rather large number of such cases. He would not operate on such cases with the specific object of improving the mental condition, but because of the pathological condition present, and as a result of such practice, he, as well as other surgeons, had seen very gratifying improvement in the mental condition. This was a subject which was totally ignored in hospitals for the insane.

Dr. **Edward D. Fisher** said that the epidemics described in the first paper were truly of a psychopathic nature, as they involved mental delusions and beliefs sometimes mixed with an idea of gain. The main body of the Christian Scientists undoubtedly had no thought of gain, and they included many refined people and men of business. The secret of the strength of this movement was to be found in the natural love for the mysterious which is deeply rooted in the human family. Our laws were sufficient to properly restrict these people, and if they overstepped the bounds, as in failing to report contagious diseases, we should make them shoulder all of the responsibility. Our opposition should only be along such lines.

With regard to the second paper, the speaker said he thought the essential feature of melancholia was the deep-seated, unreasoning mental depression. It was often because of the desire to sacrifice themselves for others that these patients committed suicide. It was utter folly to take a melancholiac out to an entertainment, because he would fail to be entertained, no matter what the surroundings. The great need was for forced nutrition and correction of the bodily functions. A fair trial should be made at the home, and if this failed, the patient should be removed and sent to some small place, preferably one having none of the features of a sanitarium.

Dr. **William M. Leszynsky** said that he doubted whether the general practitioners present at this discussion would learn anything regarding melancholia. This was not surprising, because experts often failed and admitted their inability to positively diagnose many of the milder cases. Every case of melancholia should be considered without exception as having suicidal tendencies. For this reason it was well not to treat even cases of supposed nervous prostration in the upper stories of a skyscraper hotel. In every case in which the patient's family was poor, the chances of recovery would be better if the patient were sent away to some institution. He did not think there were many cases of mental depression that were benefited by the rest cure; the majority of them were made worse thereby.

Dr. **William C. Deming**, referring to the claims of the Christian Scientists, said that they had at least served to accentuate the important influence exerted by the mind over disease.

NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

Stated Meeting, Held March 13, 1902.

Rowland G. Freeman, M.D., Chairman.

A Case of Imbecility Following Scarlet Fever.—Dr. **H. Illoway** presented an imbecile boy, who had developed what appeared to be a permanent imbecility as the result of an attack of scarlatina. Dr. Illoway was of the opinion that in this case the condition was the result of the general infection, although commonly it came on as a consequence of a meningitis.

Notes on Acute Joint Diseases of Infancy.—Dr. **T. Halsted Myers** presented a paper with this title. He pointed out that some aid in diagnosis was sometimes afforded by considering the age of the child. For example, acute articular rheumatism was almost never seen in very young infants; scurvy commonly made its appearance between the ages of eight and twenty months, and hæmophilia was commonly first observed about the close of the first year of life. Dr. Myers said that he had had blood examination made in many of his cases of joint disease, and had noted, quite uniformly, in the abscess cases, the presence of a moderate leucocytosis. This was important, because some surgeons interpreted this as meaning that the abscess had become infected, and that incision was demanded, whereas, several acknowledged authorities on blood examination state their belief that a moderate leucocytosis may be present without infection of an abscess. Acute osteomyelitis was usually produced by staphylococci or streptococci, though exceptionally the result of infection with tubercle bacilli. He had never seen a typhoid periostitis in a young infant. In cases of tuberculous osteomyelitis the joint motions were not restricted. Syphilitic periostitis usually occurred in the first two years of life, though a personal or family history was often wanting. The speaker said that he had had considerable experience with the diagnostic use of tuberculin, and felt warranted in stating that a positive reaction proved the presence of either tuberculosis or syphilis. He had seen a number of joint infections in children suffering from specific vulvovaginitis, but the affected joints were found to contain staphylococci or streptococci and not gonococci. In the mechanical treatment of the acute joint diseases of infancy, rest of the affected part and extension were the chief features. A plaster of Paris spica, with extension plasters underneath, often afforded better protection in young children than the common hip splint. While it was often desirable to resort to immobilization in the joint affections arising in connection with hæmophilia, it was hardly practicable to make use of splints, because the pressure which they produce gives rise to ecchymoses. However, in one case of hæmophilia, occurring in a boy whom he had observed for several years, effusions into the knee joint had perfectly recovered time and again without any treatment.

Chronic Joint Disease in Children.—Dr. **Henry Ling Taylor** read this paper. He said that the term chronic joint disease in children was almost equivalent to bone tuberculosis, because traumatic, rheumatic, and syphilitic infections constitute such a small percentage of the cases. Hemorrhagic and scorbutic joint affections had recently attracted much attention. Suppurative arthritis in infants was usually acute, and if treated by incision and drainage would rarely become chronic. It was remarkable how many cases of joint disease in children came to the [illegible] with a diagnosed rheumatism. It was for this reason that he desired to warn against a hasty diagnosis of rheumatism in children, especially if the affection is monoarticular. Tuberculous joint disease was [illegible] for rheumatism, [illegible] would often remain [illegible] for months, or until [illegible] symptoms appeared, as a result of some insignificant trauma. Too much weight should not be placed upon the family history, or upon the absence of pain in the early stages. The most [illegible] sign was a limitation of joint motion, caused by reflex muscular spasm. It might be [illegible] upon the hip or spine, the child would [illegible] [illegible] [illegible] that the pain had [illegible] [illegible] [illegible] [illegible] The neglect to do this was responsible for very many errors in diagnosis. In disease of the vertebrae the pain would vary with the region involved; [illegible] severe and [illegible] there were not a few cases in which the child made no special complaint, but was peevish and disinclined to move. Grunting was a prominent symptom of disease of the dorsal spine, [illegible] if persistently present the condition of the spinal column should be thoroughly investigated. The grunting breathing observed in these patients had led to the diagnosis of asthma and to many months of delay before the true condition was recognized and properly treated. Indeed, so common were errors in diagnosis in the spines of children, that it was a safe rule to make a searching investigation into the condition of the spinal column in all chronic diseases of children of an obscure nature. Another point worthy of remembrance was that pressure over the spinous processes of the vertebrae, with the object of eliciting tenderness, was incapable of giving reliable information. In hip disease limitation of the motion of the hip was the earliest and, at the same time, the most delicate test. The medical student was taught to look for hip disease when pain in the knee was complained of, but it should not be forgotten that disease of the lumbar vertebrae, as well as hip disease, may give rise to this symptom, and that pain in the knee is often absent in hip-joint disease. A study of the records brought out the interesting fact that bone tuberculosis was decidedly infrequent in persons having rachitis.

Dr. A. L. Fisk spoke briefly of cases of acute suppurative joint disease in children. Bacteriological examination in these cases would show the presence of streptococci and staphylococci, and later observations had brought out the fact that in some instances pneumococci were present, and there was a history of an antecedent pneumonia. He had treated these cases by incision and by washing out the joint with equal parts of alcohol and carbolic acid.

Dr. H. H. Berg spoke of the ease with which the milder grades of polyarthritis, occurring in children in connection with the acute infectious diseases, might be overlooked. He had used [illegible] and various internal remedies in these cases [illegible] [illegible] but had come back to the salicylates as being the most efficient and reliable. The clinical fact could not be disputed, even though we were unable to explain satisfactorily their action in a class of cases now known to be different from rheumatism. Some years ago he had reported six cases of such joint affections, because of their unusual severity. They had terminated in bony [illegible] and immobilization of the joints had been required. It was well that Dr. Taylor had laid so much emphasis on the frequency with which chronic joint disease was wrongly diagnosed, but the orthopedists were not altogether blameless, for he had known of a case of rheumatism of the hip being diagnosticated by one of these specialists as a case of bone tuberculosis.

Dr. R. G. Freeman said that while rheumatism was almost never met with in the New York Foundling Hospital, joint affections of the nature of septicæmia were not very rare.

Books Received.

[illegible] By [illegible] 376 pages. [illegible] Paris, France.

Principles and Practice of Operative Dentistry. By J. S. Marshall. 8vo, [illegible] pages. Illustrated. J. B. Lippincott Company, Philadelphia.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 15, 1902:

	Cases.	Deaths.
Measles	850	18
Diphtheria and croup	327	38
Scarlet fever	360	26
Smallpox	65	11
Varicella	132	..
Tuberculosis	243	163
Typhoid fever	22	6
Cerebro-spinal meningitis	..	5

Boer Medicine.—The Boer faith in "medicine," viz., "nasty black stuff in bottles," is almost sublime. When they swooped down on the Natal villages in the early days of the war they looted every shop they came across. Everything they could carry away they took with them, and to this drugs in bulk were no exception. Consequently, at the commencement of the campaign many of the burghers, it is reported, became in their own proper persons mere peripatetic medicine chests. An amusing instance was given recently by a trooper of the Imperial Light Horse, who was captured early in the war. On the second morning of his captivity a Boer came up to him, and, producing three medicine bottles from his bag, asked him what they contained. The prisoner uncorked the bottles, smelt them, and gave the laconic reply, "Medicine." "Oh, yes, I know that," said the Boer, "but what kind of medicine? I have a pain here," and he rubbed his hands over the region of his watch-pocket. "Would it be any good for that?" The yeoman had been lying all night in the rain, without food or even covering of any kind, and he naturally did not feel as charitably disposed towards his enemies as a dry night and a well-lined alimentary tract would have made him. The bottles the Boer showed him were covered with mud and stuff, and the labels had been washed off, and the Britisher had no idea as to their contents, so he said, "Why, yes, of course they would. I should advise you to drink the three bottles." The story ends with the highly suggestive information that the soldier never saw the Boer again! Perhaps, after all, it was just as well for that soldier.

It would appear that many of the Boers killed at this period had all their pockets full of phials and medicine boxes, and that even Private Thomas Atkins was sufficiently carried away by his curiosity to taste this loot with untoward consequences.—*Medical Times and Hospital Gazette.*

Regulations for Barbers' Shops.—The Health Board of San Francisco recommended the following series of rules to be adopted as a city ordinance. They were submitted to the State Barbers' Examiners for approval, and it was advised that they be hung in a conspicuous place in all barbers' shops. These rules seem to be both feasible and adequate:

Mugs and shaving brushes shall be sterilized by immersion in boiling water after every separate use thereof.

Razors shall be wiped with alcohol both before and after they have been used.

Hair brushes known as "sanitary brushes" must be used, after first being sterilized.

Razor strops must be kept clean, and never wiped off with the hand or blown upon with the breath.

A separate clean towel shall be used for each person.

Barbers shall not blow away with the breath any hairs after cutting, but use a towel or bulb or hair brush.

Barbers shall keep their finger nails cut short and clean; alum or other material used to stop the flow of blood shall be so used only in powder form, and applied on a towel.

The use of powder puffs, finger bowls, and sponges is prohibited.

No person shall be allowed to use any barber shop as a dormitory.

All barbers' instruments must be disinfected after using.—*Indiana Medical Journal.*

Mind Triumphing Over Matter.—In the October number of the *Sphinx*, the Liverpool University college students' magazine, Sir William Mitchell Banks brings to a close his interesting "Recollections of Student Days in Edinburgh," extracts from which have already been given in the *British Medical Journal.* Speaking of the professor of anatomy, who was then in the early stages of the locomotor ataxia which ultimately caused his death, Sir William Banks gives a graphic description of a scene in the lecture room, which paints the character of the man: One day he was a little excited over his subject, when his poor ataxic legs gave way beneath him, and his great body fell with a crash on the floor. He was speedily helped up by those nearest at hand, the table was set up, and the delicate skull bones that were on it replaced. Goodsir, though evidently agitated, steadied himself again. There was a dead silence for a brief period while he gazed intently over his favorite sphenoids and ethmoids, and then he looked up with a delighted air and said, with the greatest earnestness, "Gentlemen, there is not a bone broken." His own bones were of no moment compared to his specimens, and the notion so tickled us that we gave him a tremendous cheer.—*British Medical Journal.*

Fracture of the Forearm from Starting a Motor Car.—At the meeting of the Academy of Sciences, held on January 13, M. Sorel reported some cases of fracture of the forearm caused by starting a motor car differing from those previously reported, which were cases of indirect fracture of the lower end of the radius by rupture of the anterior carpal ligament. In the case reported by M. Sorel there was a direct fracture at the junction of the lower and middle third of the radius, owing to the blow of the crank handle on the external anterior face of the forearm while at the same time the hand was forcibly extended. Contemporaneously the styloid process of the ulna was torn off. There was thus a direct fracture of the radial diaphysis and an indirect fracture of the lower ulnar epiphysis. There was no obvious deformity of the forearm, as the shaft of the ulna, which was intact, served as a splint to the radius.—*Paris Correspondent to Lancet.*

Foreign Medical Practitioners in London.—According to the recently-issued census returns there are 4,801 "physicians, surgeons, and general practitioners" in London, of whom ninety-two are females. There are no less than 169 male and six female foreign physicians, surgeons, and general practitioners in London. Of these there are nine male and one female who are Russians; one male Russian-Pole; seven male, three female, Swedes; two male Norwegians; three male Danes; four male Dutch; one male Belgian; twelve male French; thirty-two male, one female, Germans; three male Austrians; eight male Swiss; three male Spaniards; one male Portuguese; twelve male, one female, Italians; two male Greeks; three male Turks; two male Japanese; one male Asiatic, and sixty-three male Americans. 16,107 persons living in London are returned as "sick nurses, invalid attendants," of whom 15,844 are females; three of the latter are stated to be blind; 266 "midwives" are also returned in London.—*Lancet.*

Grave Abdominal Injuries Without External Evidences of Traumatism.—R. Harvey Reed reports a series of injuries in which were grave abdominal lesions without corresponding external evidences of traumatism, yet the result in each case was fatal. In four of the cases reported there was rupture of some part of the alimentary canal. From his own experience, and from reading the [illegible] than it is the surgeon's duty to make an exploratory incision in all cases where there is grave doubt as to the real nature of the injury, and particularly so when the constitutional symptoms point to a condition more serious than is indicated by either the subjective or objective symptoms, provided the physical condition of the patient is such as to warrant such an operative procedure.—[illegible]

Definition of Old Age.—Sir Andrew Clark was accustomed to describe old age as the period of life at which a man no longer adjusted himself to his environment, and to illustrate the definition by saying that he regarded as old a doctor who expressed himself contemptuously with regard to [illegible], or who, like one of his own contemporaries, spoke of the tubercle bacillus as "lung bugs." Perhaps as regards action the best of practical wisdom in the matter may be reached by Sir James Paget's observation that the old man must not only say of one thing "I will," but "I will now," in recognition that the limit of his activities is close or approaching, and that none can say how much of any work that he defers it may ever be within his power to accomplish.—*Hospital.*

Taste or Test?—A well-known Brooklyn physician of Spanish extraction has not yet mastered the intricacies of the pronunciation of the English language. Some time ago the doctor had occasion to send a specimen of urine for chemical examination to a druggist who attends to this work for the physician. A servant was dispatched with instructions that the druggist should "taste" it. The fluid was in an ordinary wine bottle, and the German druggist eagerly swallowed a good-sized draught and immediately declared it to be the worst wine he had ever had the misfortune to sample. When the doctor informed him that it was a specimen to "test" chemically, the druggist was enlightened but not satisfied.

A Case of Abnormal Eruption of Mandibular Canine.—Mr [illegible] Whittles in a recent issue of the *Journal of the British Dental Association* records a case of the above condition. A girl six years of age had an acute suppurative periodontitis in connection with the right mandibular deciduous incisors and canine. The result was a sinus opening under the chin. Six months after a sequestrum was removed through the sinus, and the wound healed leaving a depressed scar. When the patient was ten years old the right mandibular canine erupted through the scar and was ultimately removed. The root of the tooth was considerably distorted, due probably to some displacement of the tooth sac at the time of the primary trouble.

Intravenous Infections in Foot-and-Mouth Disease.—The infection of corrosive sublimate in foot-and-mouth disease seems to have fallen somewhat into disrepute in Italy. Professor Bacelli, when asked recently in Parliament to give some statistics of the results obtained, failed to do so, although he spoke in general terms of its efficacy. At a meeting of the Piedmontese Veterinary Association a resolution was passed unanimously condemning the treatment. The method was declared to be useless, and in many cases injurious by the exacerbation both of the fever and the local symptoms and also by the production of mercurial poisoning.

Disciplining Anti-Vaccinationists.—A novel way of dealing with "conscientious objectors" has been devised by the Liverpool Stipendiary. He reads them a pamphlet, issued by the Council of the British Medical Association, containing statistics in favor of vaccination. As this occupies an hour in reading the "objectors" have to undergo what is to them an unpleasant ordeal, and we should not be surprised to find a marked falling off in these undesirable applications in consequence. We hope so, anyway, otherwise the magistrate may find it difficult to discharge his ordinary duties.—*Sanitary Record.*

Cancer in Savage Races.—The question of whether cancer is or is not common amongst savage races is of great interest, and is, perhaps, not so clearly decided in the negative as some would have us believe. Dr Long, medical resident in [illegible], said that malignant growths were common there. Dr Kerr Cross gave evidence regarding the [illegible] district, and made the [illegible] statement: "Cancer is [illegible] common," adding that he had recently seen a woman with cancer of the breast who had travelled 400 miles to consult him.—*Hospital.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended March 15, 1902:

THE RELATION OF SURGERY TO OBSTETRICS.*

By EDWIN B. CRAGIN, M.D.,
NEW YORK.

In the faculty room of the College of Physicians and Surgeons there hangs a set of certificates, bearing the date 1807, given to a student of the college during the first year of its existence. Each of these certificates represents the work of a single chair, and one of these certificates reads "Surgery and Midwifery." Although this combination is looked upon now as ancient history of amusing interest, and although in the growth and development of the college this combination existed only a few months, I desire this evening to state and defend the proposition that the relation between surgery and obstetrics is now, and in the future is likely to be, so intimate, that the best preparation for obstetric work of the highest type is through surgical training. Obstetrics will probably always be practised by the general practitioner, but, in the discussion of the subject before us, one must consider obstetrics not from the viewpoint of the midwife or the doctor who devotes little attention or study to his obstetric patient, either before, during, or after her delivery, but from the standpoint of those who consider obstetrics a science worthy of a lifetime of careful study, and the practice of the art, often associated with complications, the dealing with which calls forth the best that broadly-trained brain and hands can afford.

There are six features of obstetric work which will especially engage our attention: 1, asepsis; 2, hemorrhage; 3, lacerations; 4, obstructed deliveries; 5, eclampsia; 6, infection.

I. *Asepsis.*—It is now well understood by intelligent people, whether professional or non-professional, that the secret of success in obstetrics is based largely on asepsis. This is known theoretically, and aimed at practically, by almost every one who attends a woman in labor, but no one trained in aseptic technique can watch the conduct of a case by a man who has not had the aseptic drill of a surgical service or a similar drill in an obstetric hospital without noting the marked contrast between theory and practice. The scrubbing and disinfection of the hands, followed by the handling of non-sterile bed clothes, or non-sterile skin of the patient, is a picture often seen by the consultant in the practice of those who think they observe antiseptic precautions and are aseptic in their work, even if they have not had hospital training.

Asepsis is something which cannot be learned by reading text-books or listening to lectures. It must be learned by routine aseptic work; repeated till asepsis becomes a habit; repeated till a man develops within himself an aseptic instinct which teaches him how to render as aseptic as possible his hands and the parts concerned in operation or delivery, and after that causes him to refrain from touching anything not aseptic until the operation or delivery is completed. The preparation for and conduct during a confinement is similar to the preparation for and conduct during a surgical operation, and, in the judgment of the speaker, routine training in the latter best fits for the former.

For several years I have watched the work of young men coming to the Sloane Maternity Hospital for a three-months' service, after completion of their general hospital training. Some of these men have come from a medical service, while others have come from a surgical service, in one of the general hospitals. After careful observation, it is my firm conviction that, as a class, the men with the surgical training have not only adjusted themselves more easily to the work, but have shown better judgment and more skill.

II. *Hemorrhage.*—I shall not enter into the details of the etiology, symptoms and treatment of hemorrhage. It is sufficient to recall to your mind the fact that obstetric hemorrhage may occur either during pregnancy, during labor, or subsequent to labor; that during pregnancy, aside from other causes, hemorrhage may be due to the abnormal situation of the placenta, as in placenta previa, or abnormal situation of both placenta and fetus, as in ectopic gestation. We will discuss the last first.

Suppose any one of you is face to face with a case of ectopic gestation, with ruptured sac and intra-abdominal hemorrhage. What training will best fit you for dealing with the case? There can be but one answer. The treatment is surgical. To the man with surgical training it is simply the application of the general rule in hemorrhage: ligate the bleeding point; followed usually in this case by removal of the tube and ovary involved, the product of gestation, and the blood clots. Certainly this condition is obstetrical; just as certainly it is surgical, and needs surgical treatment.

In placenta previa, as well as in intra-partum and post-partum hemorrhages, the obstetrician is presented with a problem which needs calm judgment, quick decision, and rapid execution. He must not be disconcerted by the sight of blood, but must realize the surgical principle that if the vessel walls and the tissues about them do not contract and check the bleeding, and ligation of the bleeding points is impracticable, artificial pressure must be applied.

The version and drawing down of one leg of the child in central and marginal placenta previa, so that the thigh and half breech shall plug the cervix and lower uterine segment, is using the same principle of pressure for control of hemorrhage as when one plugs the nares for epistaxis. The rupture of the membranes in lateral placenta previa, allowing the head to descend and plug the lower uterine segment, is making use of the same principle. If in any case of placenta previa Cæsarian section seems indicated, we have surgery of a higher type. If any doubt exists as to whether or not the treatment of placenta pelvis is exposed, there certainly can be none in the treatment of post-partum hemorrhage whether that be due to uterine inertia, or laceration of the parturient canal. As in dealing with hemorrhage from a wound in any other part of the body, so, in post-partum hemorrhage one must first ascertain the source of the bleeding. Does it come from the cavity of the uterus or from a laceration of the cervix? Having ascertained the source of the hemorrhage the next step is to check it. In general surgery one ligates the bleeding points whenever practicable, but when one has to deal with a large oozing surface, gauze pressure is the method employed. Turning now to post-partum hemorrhage, due to uterine inertia with bleeding coming from the cavity of the uterus, not the cervix, it is well agreed that after ineffectual attempts to check the hemorrhage by manipulation of the fundus and the hot astringent douche, nothing serves as such a sheet anchor in the time of need as the application of the surgical principle of gauze pressure for an oozing surface, consisting here of packing the uterus with gauze. After the hemorrhage, from whatever cause, has been checked, it is generally agreed to-day that nothing will so quickly lift the woman, perhaps pulseless and apparently almost moribund, from her condition of extreme danger to that of safety and returning health, as intravenous infusion of saline solution. It is a simple procedure easily mastered but a knowledge of the veins at the bend of the elbow, and practical familiarity with the technique of the operation, make all the difference between a quick operation, with small incision and no loss of valuable blood, and an operation characterized by quite the opposite.

---

*An address delivered by invitation before the students of the Medical Department of the University of Pennsylvania, February 12, 1902.

III. *Lacerations.*—If, in spite of the firm contraction of the uterus the hemorrhage still continues, we conclude that the bleeding is from the cervix or vagina, especially the former, which has been lacerated.

Without entering the discussion as to whether or not lacerations of the cervix should be immediately sutured, it is generally agreed that lacerations of the cervix or vagina causing marked hemorrhage should be immediately repaired. The technique is not difficult, but that man will do it best who has done it frequently before, and who realizes that a cervical canal must be left allowing for drainage, as involution proceeds.

If on examination it is found that the hemorrhage is from a laceration of the parturient canal above the cervix, i.e., if a rupture of the uterus has occurred and the hemorrhage is internal as well as external, we are face to face with a surgical problem of a grave type. Realizing that the indication is usually abdominal section, with ligation of the bleeding vessel and either suture of the rent or removal of the uterus and realizing, also, that on account of the shock accompanying the condition whatever is to be done must be done quickly, one becomes impressed with the fact that he alone is best fitted to deal with the situation who is familiar with abdominal and pelvic surgical work.

Although laceration of the perineum is of less danger to life than the preceding conditions, as an indication for operation it is much more frequent, and in fact occasionally demands the attention of every one who practises the obstetric art. It may be thought that the operation for repair of an incomplete laceration of the perineum is so simple that it can be easily done by any one who has seen the operation a few times. Like all minor operations in surgery, perineorrhaphy may be rightly done, followed by no complications and by a perfect result or it may be wrongly done, with poor and dirty technique, followed by septic complications and failure as a result.

Speaking of incomplete lacerations, those, i.e., where the sphincter ani is not involved, the proper attention to the asepsis of hands, instruments and suture material, the attention to anatomical landmarks and the care to bring torn tissues into normal relation, the care in introducing each suture so that no pocketing shall be left for the accumulation of discharges. Attention to these details is found as a rule only among those who have trained themselves practically in the surgery of the perineum, and if this applies to incomplete lacerations, how much more does it hold good in the complete. We hope that none of you will be unfortunate enough in his own practice to meet with a laceration of the perineum through the sphincter muscle, but the consulting obstetrician is bound occasionally to meet with this condition in the hands of men less thoroughly trained.

Whether the patient is to emerge from her puerperium in perfect condition, and without knowledge of laceration other than that not uncommon to childbirth, or whether she is to spend months of misery, an object of disgust alike to herself and her friends, depends largely on whether her obstetrician was or was not a man trained in the repair of the recto-vaginal septum. For a man without this training to repair a complete laceration of the perineum with a good result is something the speaker has never seen.

IV. *Obstructed Deliveries.*—So long as operations for the delivery of a living child through the abdomen carried with them a mortality of 75 per cent. to 90 per cent., it was only natural that the life of the mother should, as a rule, be alone considered, and that of the child sacrificed when the parturient canal was too small for the delivery of living offspring. These times have passed, however, and with the development of obstetric surgery during the last few years, two lives demand consideration instead of one. With the record of Reynolds' nineteen consecutive Cæsarean sections without a death, and my own of sixteen with only one death, and that of a woman nearly moribund from cancer of the uterus when brought to the hospital, we realize that we are living in a new era, with new fields opening to the obstetric surgeon, but demanding from him who would enter these fields a training that is broad, and a skill in the use of other instruments than the obstetric forceps.

V. *Eclampsia.*—Although the treatment of the eclamptic seizure is largely surgical, and we shall soon discuss it, I am free to admit that the condition of toxæmia leading up to and threatening eclampsia demands the careful observation and attention to the different avenues of elimination and the detection of slight deviations from the normal, which are usually considered the work of the trained physician. This simply illustrates the fact that to be a good surgeon in any branch one must be a good *doctor*, and whatever specialty in medicine or surgery one selects, as his field of thought and work, he alone serves his patient best who realizes that his special field is but a part of the general system of his patient; that the special may affect, but is largely affected by the general. Valuable as devotion to a special field of medical or surgical work is to the world, specialism can occupy its true place, and justify its existence only, when based on the broad foundation of a knowledge and study of the patient as a whole, and the relation between the general system and the special field. For those who believe, with the speaker, that the best interests of the woman afflicted with an eclamptic seizure demand an emptying of her uterus as speedily as is consistent with the integrity of the tissues of her cervix, and lower uterine segment, it is easy to appreciate the value of experience in dilatation of the cervix, both instrumental and manual. The danger of a laceration extending into the lower zone of the uterus is well known, and is best guarded against by the training which comes from practice in dilating the cervix under various degrees of rigidity and for various indications.

VI. *Infection.*—The advantage of a surgical training in maintaining asepsis and avoiding infection has already been discussed, and we now come to the consideration of infection when that has occurred.

During the last few years we have learned that certain conditions existing just beneath the surface of the infected endometrium—such, for instance, as the blood-clots in the uterine sinuses and the infiltration of the tissue with leucocytes—are conservative in character, tending to prevent the entrance of bacteria from the uterine cavity into the general circulation. We have also learned that, by vigorous scraping and injury of this tissue, opening vessels and lymphatics, infection which before was localized may become general. On the other hand, it is generally agreed that decomposing placenta, or membranes retained within the uterus, should be removed. The problem, then, is the removal of these secundines without opening, if possible, new avenues of infection. In other words, the object desired is to remove that which should have been cast off at the time of labor, and to leave behind that which normally remains after a complete expulsion of placenta and membranes.

It is well known that, in a soft septic uterus, unless one is familiar with the feel of the uterine cavity, both with finger and curette, it is easy to mistake uterine wall for foreign material, and scrape not only beyond the limit of safety, but even through the uterine wall. The man will accomplish the desired result more thoroughly, more rapidly, and with less injury to the endometrium and uterine muscle, who has trained himself in the feel of the uterine cavity under varying conditions.

It is generally agreed that major operations for puerperal infection are not often indicated, but collections of pus in the Fallopian tubes, or in the wall of the uterus, sloughing tumors, and other conditions complicating the puerperium, sometimes demand surgery of the radical type.

One best understands the preparation needed for obstetric work of the higher type by considering the demands made upon the obstetric surgeon at the head of any of the good maternity hospitals of the country. He is not only called upon to superintend the conduct of normal labors, but to deal with all complications as they arise, whether it be in the hard parts or in the soft; whether it be in the parturient canal, or within the abdominal cavity.

One cannot consider the growth and development of obstetrics during recent years, especially along surgical lines, without feeling that its limit has not been reached, and the speaker will, perhaps, be pardoned for a glimpse into the future, which to him seems justified. It seems to me that in the near future the skilled obstetrician will not be thought to have finished his work until the parturient canal of his patient is restored to as good a condition as existed prior to the onset of labor. This implies not only the immediate repair of lacerations, when indicated, but also the secondary operation, if for any reason the primary was not performed, or was not successful. The difference in the two operations is chiefly one of denudation. In the immediate operation the parts are already denuded and ready for approximation; in the secondary operation, denudation must be the first step. The value of experience in secondary operations, when performing the primary, has already been referred to. It is equally true that familiarity with the appearance of the raw surface just produced by a laceration greatly aids in the secondary operation.

There is one other condition of the uterus which, in the future, I believe will be regarded as falling within the sphere of the skilled obstetrician. I refer to a displacement of the uterus beginning in, or recurring during, the puerperium. The fact that such displacements are most likely to occur when the uterus is large and the ligaments are relaxed is well known. That these displacements are more easily corrected soon after their occurrence is also well known; it, therefore, seems only rational that the obstetrician should be trained in the maintenance of the normal position of the uterus during its involution.

The test of every operation for the correction of a displacement of the uterus, aside from the relief of symptoms for which the operation was performed, is non-interference with the normal course of a subsequent pregnancy and parturition The man who has the best opportunity to judge of the effect of different operations upon these conditions of pregnancy and parturition is the obstetrician. I believe, then, that I am not extending his field too far, when I express the belief that the time will come when the care of cases of displacement of the uterus, which have been neglected during the puerperium, or which failed to respond to treatment during this period, will be considered the legitimate work of the skilled obstetric surgeon, and that, too, whether the case needs pessary or operation.

Gentlemen, my object this evening has been to throw upon the screen a picture of obstetric work of what I have called the higher type, and to inspire within you respect for a branch which some of you may have thought small and narrow.

The branch is no longer small, and it is only narrow when you make it so. With its ever-increasing literature, its problems extending into the realms of biology, physiology, and bacteriology, and its technique demanding years of training before proficiency is attained, certainly its fields are broad enough to inspire conscientious preparation and lifelong devotion.

Realizing that the growth and development of obstetrics during recent years has been largely along surgical lines, and realizing, too, the anxiety of medical students to best prepare themselves for their life work, it seemed to me fitting that you should have impressed upon you the relation of surgery to obstetrics.

62 West Fiftieth Street.

Creosote in Pneumonia.—Dr. I. L. Van Zandt of Fort Worth, Tex., is preparing a statistical table showing the results of the treatment of pneumonia with creosote or creosote carbonate, and asks physicians who have given the treatment a trial to send him, on a postal card, during April, 1902, the number of cases treated, and number of deaths, whether of record or on approximation. The questions are as follows: (1) Do you believe creosote ever aborts pneumonia? (2) Do you believe the majority of cases are mitigated by it? (3) Have you found cases which, having plenty of time, were entirely uninfluenced by it?

THE STUDY OF QUARANTINE IN THE LIGHT OF MODERN PROGRESS.*

By ARTHUR H. GLENNAN, M.D.,

SURGEON U. S. MARINE HOSPITAL SERVICE; CHIEF QUARANTINE OFFICER FOR THE ISLAND OF CUBA.

The meaning of quarantine in the original acceptation of that word has so wholly changed with the progress of sanitary science as to be inadequate to the demands of modern usage, and incapable of covering the present field of restraint of epidemic disease.

Different definitions have been made the outcome of differing interpretations of a law none too clearly defined because of the varied applications of quarantine, for instance: "The time during which a vessel from ports infected with contagious or epidemic disease is required by law to remain outside the port of its destination as a safeguard against the spread of such disease." This is decidedly inadequate as referring only to maritime quarantine, while we have land, interstate, municipal, railroad, house and room quarantine.

Another rendering of the meaning and scope of quarantine reads thus: "The length of time required to insure immunity after exposure, or the length of time necessary after an attack to render the disease innocuous." To our sense, however, a more comprehensive exposition has been given by Surgeon-General Wyman of the Marine Hospital Service: "The adoption of restrictive measures to prevent the introduction of diseases from one country or locality into another."

It is a long step from the time of Moses, the lawgiver and sanitarian, who decreed that the unclean should be kept apart and the leper remain outside the gates, to the time when Venice, in the fourteenth century, first quarantined vessels for forty days against the plague.

Hence we have the term lazaret or lazaretto, from the house of St. Lazarus, located upon a small island near that city. The sanitary laws of Moses provided for the cleansing and disinfection of clothing and habitations, and their destruction when necessary, a very early recognition of the necessity of isolation and disinfection.

The ancients offered sacrifices to their gods during times of epidemic pestilence to appease offended deities. In later Christian times fastings, prayers, and religious processions were made in an intercessionary way, to be delivered from so-called "visitations of Providence." At the same time fires of pitch-tar and other material were burnt upon the streets to purify the air and dissipate the plague, while herbs and odorous drugs were carried upon the person to prevent infection.

Intermixed with the appeals for spiritual help and crude physical endeavor to be free of pestilential disease in the Biblical account of the race, appears the idea that fear, sin, disease, and death are intimately related, the result of wrong living.

Out of all this error of thought modern sanitary science has developed the fact that Providence does not specially direct or send disease and pestilence, they are simply the result of departure from fixed laws of proper sanitary environment.

Out of this grew the necessity for a quarantine against a country or locality which neglected these laws, developing into a maritime quarantine in the narrower sense of self-protection and rigid exclusion of the person and effects of the offending neighbor for an indefinite time, without regard to the practical methods of purification or the limitation in the incubative period of disease. For the same reason the "sanitary cordon" was established upon land to retain the limits of pestilence or prevent its spread and introduction: fear and the shotgun upon the one side, and terror and disease upon the other, struggling to escape.

In the light of modern progress we have a better understanding of sanitary laws and the origin and propagation of disease. As we reach out, understanding and destroying the foci of disease, quarantine as a means to an end is proportionally relaxed, and finally becomes unnecessary.

Quarantine is eminently dependent upon the practical value of scientific investigation of disease, which must correspond to definite methods and rules of procedure in order to meet confirmation and acceptance. Without these conditions arise useless discussions and opinions of that which should be a matter of fact.

The personal equation and bias of the observer must be eliminated and mathematical precision introduced to make any conclusion of scientific value, therefore the casual observations of the earnest general worker have seemed of merit, and often did come very near the border line of truth, but without systematic classification or method, they are useless to-day, while the careful work of scientific investigation cannot be cast down by these unformulated opinions as offered in the medical magazines, or the relating of personal opinions and hearsay evidence in medical society meetings.

We are all familiar with the earnest work pursued by exact methods in Havana by Drs. Reed, Carroll and Agramante as to the propagation of yellow fever by the mosquito; the discovery of their relation was undoubtedly noted before by Dr. Finlay; but I refer more particularly to the scientific demonstration of the fact. The conclusion from all work of this character must correspond with the demonstration, and undue claims be avoided; while the conclusions thus logically drawn from it must stand. "Truth is mighty and will prevail!"

All the limitations and relaxations of modern quarantine are founded upon confidence, first, in the knowledge arrived at by investigation as to the origin, growth and progress of epidemic disease, and, second, its arrest and destruction at the quarantine barrier, with reasonable assurance of safety after release.

The improvements in quarantine methods have kept pace with the development of our knowledge of the origin and propagation of disease and cause of epidemics, while the methods of prevention have not generally exceeded the value of the protection afforded.

All the devices and inventions of modern progress have been applied to the uses and modification of quarantine. The telegraph and cable give notice to the health officer of the conditions and prevalence of disease in ports of departure, and the fluctuations of epidemic disease in distant countries, thus affording ample time for protection with the least interference to commercial interests.

Chemistry gives us the most efficient agents for the destruction of the germs of disease, and bacteriology the limit of time in which they can be safely applied, reducing the old period of forty days' detention to possibly an equal number of hours.

All the modern appliances are to be found upon the disinfecting steamer *Sanator*, located in Havana harbor for the past two years, the property of the United States. This vessel is conceded to be the most complete and compact disinfecting floating plant in the world. Its use has demonstrated the value of disinfection in ports of departure, while the incubative period of disease is, all or in part, undergone afterwards at sea. With the certificate of disinfection taken from this initial point, the quarantine officer at the port of arrival carefully inspects the vessel's personnel, and if found favorable, releases the vessel with confidence. This more recent process in the treatment of vessels and cargoes is a great commercial advantage, and it is a satisfaction to know that the majority of steamship companies and common carriers now distinctly recognize the financial benefit of rational quarantine methods as a protection to their interests.

---

*Read before the International Sanitary Congress, Havana, February [illegible] 1902.

The best result to be obtained from international sanitary conferences should be based upon informatory principles, and not the imposition of too many rules and regulations, to which the various countries are not prepared to subscribe, because quarantine is progression, bespeaking a nation's growth towards higher ideals.

The diffusion of sanitary science and knowledge of hygiene has been rapid in the past few years, and is now known to a greater or less extent in all the countries of the world. Its practical application has been demonstrated in this fair city of Havana, in the eradication of yellow fever, by the application of methods of procedure deducted from scientific investigation under the administration of Dr. Gorgas. In only the same way will other quarantinable foes be conquered, and the restrictions of quarantine disappear. Education and understanding, right thinking and right living, will hasten this result to the individual and the community.

The student of history will observe that strife and war has always bred pestilence from time immemorial, consequently international conferences for arbitration are an aid to international sanitation. So, also, has port and municipal sanitation come to be interwoven in international commercial agreements; the one an adjunct and an aid to the other. This has just been recognized at the recent Pan-American Congress, which met in the city of Mexico, where the following rules were formulated and recommended by the Signatory Republics:

"1. All matters relating to maritime quarantine should be intrusted to the national governments, which shall have the sole right to institute maritime quarantine; to establish the necessary quarantine stations, both land and floating; to define the length of time during which a vessel may be detained and to adopt such measures as may be deemed necessary to prevent the introduction of contagious disease.

"2. In the port of each of the signatory States there should be established two kinds of quarantine—first, the quarantine of inspection or observation, and, second, the quarantine of detention and disinfection.

"3. The signatory parties agree to recommend that prohibitive quarantine on all kinds of new manufactured merchandise between ports and territories of the parties shall be abolished.

"4. The signatory parties hereby agree to coöperate with and lend every possible effort of the municipal, provincial, or local authorities within their respective limits, to the end that efficient and modern sanitary conditions may be obtained in all ports and territories of each, for the purpose that quarantine restrictions may be diminished to a minimum and finally abolished.

"5. The signatory republics further agree that it shall be the duty of their respective health and quarantine organizations to promptly notify the diplomatic or consular representatives of the signatory republics stationed within their territory of the existence and progress within their sovereign limits of the following diseases, namely: cholera, yellow fever, bubonic plague, smallpox, or other serious pestilential outbreaks. It shall be the duty of the sanitary authorities in the respective ports to note on the bills of health the transmissible diseases which may exist in said ports prior to the sailing of the vessel.

"6. In order to bring health and quarantine organizations more closely together for mutual benefit and international coöperation, a general convention of representatives of these organizations shall be provided for as hereinafter specified.

"In order to promote the above aims, it is recommended that an international sanitary committee shall be established, whose membership shall consist of not more than five delegates appointed by each republic; said delegates to be selected from the respective health and quarantine organizations of each republic, so far as practicable.

"That a general convention of these delegates shall be held once every two years, in which convention one delegate may represent more than one republic, the voting to be by republics, each republic represented having one vote in the convention.

"The first general convention shall be called by the President of the United States, one year from the date of the adoption of these resolutions by this conference, and the meeting place or places of subsequent conventions shall be determined by the general convention.

"The executive board shall consist of five members, to be elected by the general convention, which, with the Surgeon-General of the Marine Hospital Service of the United States as chairman *ex-officio*, shall maintain a permanent international sanitary bureau at Washington, D. C."

The functions of the general convention shall be advisory in character. They shall make manifest, practical, and active the latest scientific knowledge which the world has obtained in sanitation, to the end that the public health may be protected, and that commerce may be facilitated. The general convention assembled, or, in the interim, the executive board, shall have the authority to appoint subcommittees or experts to investigate, in coöperation with local authorities, into the sanitary condition of ports or places where pestilential diseases prevail, and to inquire into any other special conditions affecting the health of the American republics, and to maintain communication with the various health organizations for the purpose of recommending sufficient measures in all emergencies.

The salaries and expenses of the delegates and experts of each republic are to be paid by the respective governments which they serve. The office expenses and the expense of special investigation, as well as publication, translation, and distribution of reports, are to be paid from a special fund created by annual appropriation by the signatory republics, made on the same basis as is in force for the maintenance of the Bureau of American Republics. It is further recommended that the facilities of the Bureau of American Republics, under the direction of the Secretary of State of the United States, be utilized by the general convention and its Executive Board, for the correspondence, accounting, auditing, and disbursing and preservation of the archives incident to the administration of the proclaimed purpose of the convention.

These rules,* formulated at the City of Mexico, are quoted in full; are offered as a fitting summary of the present state of sanitary thought in the light of modern progress, and worthy of consideration and adoption by this International Sanitary Congress.

---

*Note.—The rules were unanimously adopted by this Congress at a special meeting of the delegates.

A FATAL CASE OF GANGRENOUS APPENDICITIS WITHOUT ONE CARDINAL SYMPTOM IN THE COURSE OF THE DISEASE.*

BY [illegible] EVANS, M.D.,
NEW YORK CITY.

To reiterate the usual picture of appendicitis, namely, pain, tenderness, rigidity, rapid pulse, etc., which has been set forth by the most skillful physicians of our time, is not the purpose of this report, but to show the inadequacy of the picture to represent every case.

The patient, C. P., was nine years of age. Her father was subject to bilious attacks when young, and has always had more or less tendency to gout. The patient had vomited frequently, and for the past three or four years of her life was troubled occasionally with moderately severe attacks of facial eczema. Otherwise her history was negative up to a year and a half ago, when, within a period of five months, she was ill three times, her illness being characterized each time by prostration, nausea, vomiting, rapid pulse, some temperature, obstinate constipation, and slight soreness over the abdomen. In the last one of these attacks the abdomen was examined thoroughly. There were no tympanites, no rigidity of recti and no especial tenderness anywhere. The cause of these symptoms, however, could not be found. Each illness continued about one week, followed by a slow convalescence. During her last illness serious attention was directed towards the appendix, although there was a total absence of all cardinal symptoms of appendicitis.

The illness which is the subject of this paper was preceded by a week or two of ailing, during which she had no appetite, was very constipated, grew pale, complained of being tired without sufficient reason, and now and then had severe headaches.

About noon, January 22, she was put to bed, as she had complained of an intense headache during the morning. I saw her in the afternoon and made a thorough physical examination of her. There was no temperature, but the pulse was a little quickened. The tongue was dry and coated. The examination of the heart, lungs, liver, spleen and nervous system, was negative in its results. The examination of the abdomen revealed nothing. Her throat was dry and somewhat reddened, due to a recent cold. The patient was perfectly comfortable and wondered why she was compelled to be quiet.

The morning of the 23d found her with a normal temperature and a pulse of 98, whose quality was decidedly thin. The headache was better, but the tongue was more dry, and its coating, instead of covering the whole dorsum of tongue, as it did the previous day, was confined more to the middle, leaving a very red margin at the edges and tip. Her breath was very bad and she was vomiting frequently, yet she asked for food. Her bowels had moved well and her mind was cheerful. A physical examination revealed nothing new.

In the evening her abdomen was examined again, but there was neither soreness nor tenderness found. The stomach, however, was still irritable. The vomitus was green, watery, and of normal odor.

The next morning, January 24, her temperature was 99°, pulse 112 and more thin and wiry. Nothing could be retained on her stomach. She passed rather a sleepless night, begging constantly for water or broth. Her face was drawn and pinched and her skin was dry and sallow. She was able to lie on her side as easily as on her back. There was a frequent desire to pass urine, which, on examination, was found normal in every way.

The evening found her with a temperature of 99.8° F., and a pulse of 120. She was much weaker, although her stomach was less irritable. She complained a good deal of headache during the day, and said she could not bear the light. She complained of her abdomen feeling sore for the first time. Palpation revealed a more or less general hyperæsthesia all over her body. There was no tenderness anywhere in the abdomen, and another complete physical examination left me as completely in the dark as ever. Her spirits were wonderfully maintained, and she was ready to smile or answer any questions put to her.

On the morning of the 25th her temperature was only 99.8°, though her pulse had shot up to 132, and its thin, thready quality was more than marked. The lips, as well as tongue, were very dry, and her thirst was no better, despite every means to alleviate it. She passed another very restless night. Her stomach was still irritable. Her face was somewhat cyanotic, and she was emaciating rapidly. Nothing was learned from another physical examination. The abdomen was slightly sore, but no more than the rest of the body. Pressure at McBurney's point elicited some pain, but of a very indefinite character, and in all probability it was due to the hyperæsthesia of skin, as there was no rigidity of either recti, and all methods of detecting pain in this region proved futile. She wanted to lie on her back most of the time. Dr. W. T. Bull was called in consultation, but could find no cause for her condition.

In the evening a blood count was made, and the leucocytes were found to be 19,600. A rectal examination disclosed a soft fluid mass in Douglas's culdesac. The child's resistance prevented drawing any certain conclusions.

The 26th saw a marked change for the worse. Her temperature in the morning was 102.6°, indicating for the first time some thermic disturbance. The pulse, worse than ever, rose to 136. A physical examination left us more mystified than ever. Her abdomen was still very sore, and she dreaded having any one touch it, but when she was being examined it was surprising what little resistance she offered. She was examined per rectum, under an anæsthetic, by Dr. W. T. Bull, Dr. L. Emmett Holt and myself, but nothing pathological was found. During the day she was seen also by Dr. Jos. E. Winters and Dr. E. G. Janeway. They found nothing whatever to explain the profound toxæmia which was now so evident. There were two very offensive movements from the bowels during the day. The pulse grew more and more rapid, reaching 156 by night, and on the 27th, about 11.00 A.M., three hours before she died, it had reached 172. The temperature after once reaching 102° remained high until she died, being 105° at one time. The abdomen was watched carefully until the end, but divulged nothing different from what had previously been found. She died at 2.30 P.M., January 27.

To Summarize.—This patient was sick five days. Every twenty-four hours marked a decided advance in the pulse and toxæmia—the pulse increasing about 20 to 30 each day. The temperature remained practically negative from the fourth day after beginning of first symptoms until thirty hours before death, and there was not a cardinal symptom of appendicitis or peritonitis at any time.

Autopsy made by Dr. Harlow Brooks seven hours after death.—The body is that of a slight, but well-formed female child about nine years old. Rigor mortis is present in both extremities and in the muscles of the trunk and neck. It still retains some animal heat. The tips of the fingers and the toe nails are moderately cyanosed. The mucosa of the lips is somewhat bluish, but the skin of the face is white and clear. The integument, as a whole, is anæmic and free from any manifestation of disease, except that there is slight posterior cyanosis. The abdomen is not distended, and is but slightly tympanitic.

---

*Read before the Pathological Society of New York City.

The amount of subcutaneous fat is fairly abundant, but it is highly colored, as though recent absorption had been rapid. The musculature of the thorax and abdomen is well developed and is in normal condition.

Both visceral and parietal peritoneum is covered with a thick but tenacious exudate—apparently representing an early stage of peritonitis, though the capillaries of the peritoneum are but moderately injected, with exceptions to be noted later.

The stomach is small, and contains a small amount of slightly bile-stained fluid. It is otherwise in normal condition.

The jejunum is normal throughout, but is moderately distended with gas. It contains a fluid substance, which contains rather more than a normal amount of mucous (calomel?).

The ileum is also normal except for about 7 cm. of one of its lower folds, which lies in immediate contact with the cæcum and appendix. This portion of the gut encloses a very fetid dark-colored substance, and the walls of the gut at this point are dark, and the capillaries congested.

The caput coli is normal, though quite markedly distended with gas, except where the appendix is given off. Its peritoneal coat is congested, dark in color and approaches the appearances now to be noted in the appendix.

The vermiform appendix is 6.2 cm. long. It is of large lumen, averaging about .7 cm., but at its root it measures 1 cm. in diameter. It is free from adhesions, but is stiff, almost erect, standing up from the cæcum and resting upon the portion of gut described. It is dark bluish in color at the tip, this hue fading to a fairly bright pink at the base. The capillaries of the peritoneal covering are much injected, and appear on the dark gangrenous surface as bright red lines. The peritoneum is also covered with a recent thin purulent exudate. The lumen of the appendix is distended with a thin, dark-colored pus, and the mucosa is found gangrenous in spots, though no points of perforation through the peritoneum are present. Many deep ulcerations down to this coat are found. No foreign bodies are present in this portion of the intestine.

The colon is distended with gas in the ascending and transverse portions, but is flaccid in the descending part. It contains a considerable amount of fluid fæces.

The mesenteric lymph nodes are almost universally enlarged. Their tissue is firm and apparently fibroid. There are no evidences of tuberculosis, and the cervical nodes are not found enlarged.

The ovaries are large, and, together with the tubes and uterus, are perfectly formed and entirely normal for a child of this age.

The bladder contains a small amount of urine; it is normal.

The kidneys are of normal size. Fœtal lobulation is not evident, and the organs present no gross evidence of disease except for a slight injection of their capillaries.

The adrenal bodies are large and apparently natural.

The pancreas is large. No lesion is present.

The spleen is enlarged about one-half volume. Its tissue is recently congested and its pulp abnormally soft. The malphigian nodules are large and very clearly seen.

The liver is of usual size. It presents nothing abnormal. The gall bladder contains a few cc. of bile. The duct seems to be in a natural condition.

The heart is large, and its walls are relaxed and quite soft, more so than normal. It contains a moderate amount of dark fluid blood and post-mortem clot. The valves, coronaries and the arch are in natural condition. The myocardium is pale in color and somewhat swollen, apparently showing a recent parenchymatous degeneration.

The pleural cavities are free and normal. The lungs are normal throughout, except that there is slight hypostatic congestion of the posterior portions of both lungs. There are no areas of bronchopneumonia and no scars of the apices.

Anatomical Diagnosis.—Gangrenous appendicitis, probably an acute attack following chronic appendicitis. Localized incipient gangrene of the small intestine. Acute parenchymatous myocarditis.

Miscroscopic Examination.—Heart: In places the heart muscle cells show a pronounced granular degeneration; the granules are small, highly refractive, and clearly not fatty. The interstitium of the heart shows no alterations except in the region of certain of the small bloodvessels, where areas of small round cell infiltration are frequently found. Otherwise the sections show nothing abnormal.

Lungs: The bloodvessels throughout are very much congested, and are filled with a fine granular detritus. Other sacs are partly filled with large œdematous, desquamated cells, evidently from the walls of the air space. None of the sacs contain red blood corpuscles, though a few enclose some leucocytes. Evidences of true inflammation are entirely wanting.

Liver: Many of the parenchymatous cells, particularly those about the intra-lobular veins, show a quite advanced fatty degeneration, but the cells in the periphery of the lobules are, for the greater part, in natural condition. The bloodvessels are moderately congested. There are no changes in the interstitium. There is a slight infiltration of small round cells beneath the capsule in places.

Kidney: There is an extensive sub-capsular infiltration of small, round cells, together with extravasations of blood over the entire capsule where examined. The cells of the convoluted tubules are swollen, very granular, and many of them are largely disintegrated. The degenerative changes are most apparent in the peripheral parts of the ascini, but are present in all parts of the cortex.

Mesenteric Lymph Nodes: There is extensive congestion of the vessels, and the parenchyma and cortex are both extensively infiltrated. In places necrosis is taking place, and in these areas numerous bacteria are demonstrable.

Appendix: The epithelial lining of the appendix is desquamated in all the sections. The glands are also broken down, and the inner portions are thrown off with the internal epithelial coat. The lymph follicles of the mucous layer are intensely inflamed and areas of necrosis are frequent. The most extensive inflammatory changes are found in the submucous and muscular coats, where the infiltration of small round and pus cells has extended deep down, and in many places through to the serous coat, which is infiltrated and in places necrotic. All the vessels are greatly congested, and in many the surrounding tissue has become the site of extravasations of blood cells, while nearly all are surrounded by areas of small, round cells. In many places the sero-fibrous coat has become completely eroded.

but where it still remains it is found to be necrotic and infiltrated with bacteria and pus cells. Most of the vessels of this outer coat are thrombosed.

Sections stained for bacteria show the presence of very numerous bacteria, no particular sort apparently predominating. Bacteria are most frequent in the necrotic sero-fibrous coat and in the peritoneal exudate which covers the portions of this coat which still remain.

This case possesses some extraordinary features.

At the post-mortem examination there were found none of the usual factors causing appendicitis; the appendix was straight, of large lumen, unobstructed by any foreign body, adhesions or fecal formation.

There was a bacterial infection of the peritoneum without perforation of the walls.

There was gangrene in that part of the lumen touching the appendix.

The infection killed the patient before peritoneal conditions had developed.

Most extraordinary of all is the fact that up to its fatal termination it had not shown one of the cardinal symptoms of appendicitis.

A careful search of appendiceal literature has been made with the purpose of extracting only those facts, suggestions and observations which pertain to this case. Although no similar case was found, there were many which resembled it in some features. The material gathered is classified under the usual headings, with no intention of offering a treatise on appendicitis, but of presenting a compilation of those facts which have some bearing on the present instance.

Etiology.—The appendix is a functionless vestige, of parts once useful in our prehistoric ancestors, possessing necessarily a low vitality, and but feeble resisting powers. It is a test-tube containing a more or less stagnant culture media, which is the normal habitat of the bacillus coli communis and other bacteria.

It is the frequent habitat of the thread-worm.

It is a glandular organ, sometimes called the abdominal tonsil, and as such is subject to follicular, infectious, exudative, and ulcerative inflammations. It frequently contains foreign bodies, such as apple pips, seeds, bristles, shot, bits of bone, enteroliths.

It is said by Flint to be deficient in circular muscular fibers, rendering it unable to expel foreign bodies which may produce pressure, oligemia, obstruction and conditions favorable to virulent action of the contained bacilli.

It has a valve (Gerlach's), which is often inadequate and subject to conditions of cæcal mucous membrane. With the cæcum it lies on the ileo-psoas muscle, which is in more or less constant motion (unrest of ileo-psoas).

It is dependent, so that its free end roams at will, gets twisted, bent, caught in hernias, adhesive bands, etc.

It is out of the fecal current.

It has but one artery, which is terminal in the male, but anastomoses, with a branch of the ovarian in the female—hence anything affecting the free circulation of blood in this artery, such as a bend, a twist, pressure from an inflamed mesentery, obstruction from within, as a thrombosis or embolism, will affect vitally the nutrition of the appendix and prevent the polynuclear leucocytes from reaching the scene of action to protect the organism with their nuclein.

It has a mesentery attached usually only to the inner two-thirds, which is often too short, causing a sharp bend of the appendix, and, owing its attachment to the ileum, it will drag on the appendix when that part of the intestine is filled with feces or gas, thus causing a limited blood supply, congestion, and a catarrhal inflammation.

It has a lumen which is small when compared to the thickness of its walls, hence the slightest congestion or inflammation quickly obliterates its lumen and dams back the stagnant germ media.

The nerves are frequently atrophied from a chronic interstitial neuritis.

Bacteriology.—The bacillus coli communis and other bacteria are perfectly harmless in ordinary healthy conditions of the intestinal tract, but they become intensely virulent when they assume pathological activity.

They assume this activity wherever a "locus" of least resistance is present.

This "locus" is offered more frequently in the appendix than in any other organ of the body, owing to its histological and anatomical structure.

It has been fully demonstrated by Welch and Malvoz that bacteria can pass through an inflamed intestinal coat and cause peritonitis without perforation of the walls. This is also proven by Willy Meyer's case.

The three most active bacteria in appendiceal inflammations are the bacillus coli communis, the streptococcus pyogenes, and the staphylococcus pyogenes.

Infection, at first, is always mixed, and in the early stages the streptococcus has most to do with the production of severe symptoms.

The streptococcus pyogenes and the staphylococcus pyogenes are the most virulent. The bacillus coli communis infects more widely, leading to pylephlebitis, abscess of liver, etc.

The lymphatics are very active in children and bacteria work best in virgin soil, hence infection is more intense in children.

Pathology.—Suppuration may occur in the coats of appendix, or even necrosis, without necessarily bursting through the peritoneal coat or into the lumen of the appendix, but though they may appear slight to the naked eye, they are frequently followed by fatal peritonitis.

The rupture or perforation of an inflamed appendix is more virulent than ordinary fæcal extravasation, for the bacteria have already had full opportunity to grow and produce toxines. Gangrene is due to thrombosis of the artery, caused by the infectious process.

Gangrene usually occurs in twenty-four to thirty-six hours from the beginning of symptoms.

White reports a case where the gangrene and infection were so overwhelming that the adjacent part of ileum was gangrenous.

Semiology.—The gravest cases are initiated by a complexity of symptoms, which furnish no indication of the lurking danger hidden, and the mild cases present themselves attended by symptoms indicative of a far graver condition than really exists. Senn says: "I have operated on many cases in children in which constitutional symptoms were of severe type and found, to my utter astonishment, a plain case of appendicitis without perforation or peritonitis to any extent."

Taylor reports the case of a healthy man who had an appendix buried in a small abscess, who could knead his abdomen all over without the slightest pain or discomfort; also that he has seen slight local change in the appendix with manifestations of most virulent ptomaine poisoning.

He explains this by saying that a boil may give one man only a little local discomfort, while in another it causes most severe constitutional disturbance.

This difference has something to do with the virulence of the ptomaines generated, their absorption, the resistance to absorption, or their rapid elimination.

Keating says that young do not point to the region of the appendix as an adult. The physician is often compelled to find out for himself.

Treves reports one man as spending hours massaging his own abdomen, and another as drawing frequent attention to the absence of tenderness by slapping his abdomen, and both had septic peritonitis.

Tubby says that pain may be absent in gangrenous appendicitis, because the appendix is dead, nerves and all.

Mynter reports a case where a patient with gangrenous appendicitis lay quietly in bed with a normal T. P. R.; also that death may take place in appendicitis before any macroscopical lesion is present and before peritonitis occurs.

Fowler says, "A remission of all symptoms of the first, second, and third stage, save local tenderness, may take place, yet the disease goes on to a fatal termination."

Deaver says, "Tenderness is always present, but if, however, septic absorption has progressed so far that paralysis of nerve filaments has been caused, we may find tenderness has disappeared without any diminution in the progress of the disease." Also, "Abrupt cessation of pain indicates gangrene."

Dieulafoy states that the virulence of infection may suffice to kill a patient, while peritoneal symptoms are quite subsidiary.

In the foregoing we find, with one exception, a precedent for each of the unusual features of this case, the exception being that none of the cardinal symptoms of appendicitis were indicated, while in all others a diagnosis of appendicitis or peritonitis could be made some time during the course of the disease, from the presence of one or more of the cardinal symptoms.

This case declares that an infection can exist in the appendix which will end fatally, not only before peritoneal symptoms develop, but before giving any indication of its source. Therefore, if in the presence of constitutional symptoms of toxæmia, the source of which cannot be found, there exists the merest suspicion of abdominal involvement, is it not justifiable to make an exploratory incision for the purpose of diagnosis, and of further interference if necessary?

The Antitoxic Function of the Liver During Pregnancy.—Emanuele Viola has found, through his experimental researches, that during pregnancy the protecting power of the liver is diminished. This is shown by the fact that its neutralizing poweris diminished by nicotine, strychnine, and atropine, that the amount of glycogen is diminished during pregnancy, the amount of fat increased, and that the urine gives the signs of hepatic insufficiency. The liver, in fact, is in a pathological condition, and that the individual can remain healthy in spite of this, can only be accounted for by the supposition that some other organ acts in a compensatory manner. This organ the author thinks may be the spleen. The kidneys, also, are compensatory organs, and, for the reason that so much extra work is thrown upon them, are in a condition of increased vulnerability—hence the tendency to renal lesions. The depression of liver function is the chief cause of the unstable functional equilibrium during pregnancy, and this accounts for the special liability to contract marked conditions, and gives the anatomical basis for the occurrence of eclampsia.—*La Sperimentale.*

COSMETIC CONSIDERATIONS NOT THE ONLY ONES IN CASES OF STRABISMUS—THE IMPORTANCE AND THE POSSIBILITY OF SECURING BINOCULAR VISION.

By RICHARD H. DERBY, M.D.,
NEW YORK

WHATEVER the method of operation adopted in any case of strabismus, the result, both cosmetic and visual, may, and generally does, depend very largely upon what we may designate as the orthoptic treatment. Probably no ophthalmic surgeon would undertake the surgical care of a case of strabismus without a full and accurate knowledge of the refraction and the acuity of vision of the strabismic eye. It may be that before the tenotomy an effort has been made to relieve the strabismus by the use of glasses, or that after the operation itself a greater effect has been sought by properly adjusted lenses. So far as the writer has been able to observe, it is not the practice of many, at least of our ophthalmic surgeons, to avail themselves of methods of ocular exercise, which, practised before the operation, tend greatly to add to its success, and which, carried out after the operation, materially increase its effect. The strabismic eye is often amblyopic, but as is now well known, in many cases the amblyopia is such that patient treatment, especially when the subject is a child, can do much to ameliorate the condition.

The amblyopia in cases of monolateral squint has been described under at least three different forms. In the first the acuity of vision is diminished, but there is no change in the conductibility of the retinal elements. The condition is one of dulness of the retina. Again, there is a form of amblyopia in which the power of fixation is impaired. The patient makes tentative movement with the macula, which seems to be losing its predominance over neighboring portions of the retina. In the third form the inner half of the retina has better vision than the fovea.

In the first form, it is common enough to have an improvement of the vision after the tenotomy. In the second form the improvement is not immediate, but comes gradually. In the last form the chances of improvement of vision are small.

It is in the second category of amblyopia, and especially in the case of young children, that results can be secured by treatment. Of the first importance is the complete correction of the refractive error. While in practice I have learned to depend largely upon the ophthalmoscope, the ophthalmometer, and the use of glasses in estimating the refraction, it is not so with the strabismic child. Nothing less than repeated and complete atropinization is safe here. The ametropia once corrected, the isolated training of the amblyopic eye should be begun. To this end the closely fitting screen over the well eye is necessary, and for a half hour at a time daily, and in some cases twice in the day, the deviating eye is to be exercised. Exercises in reading and in writing under these conditions are to be insisted upon.

The following histories illustrate the advantage to be derived from long-continued daily exercise:

CASE I.—Julia W., a girl ten years old. Intermitting divergent strabismus of left eye. The right eye emmetropic, vision ten-tenths. The left has mixed astigmatism—1.50 Dc. (0°) combined with +4Dc. (105°) V = one-tenth; the vision, however, is not lasting, and on looking at the test-types, the letters soon disappear. There is central fixation. Patient was directed to make daily exercise, the right eye under a screen and the refraction of the left completely corrected. The vision of the squinting eye rose slowly, and the best attained was three-tenths, by means of Monoyer's fourth line. Together with the monocular exercise, the use of the stereoscope was continued, and at the present time, more than twenty years after the patient was first seen, there is dynamical equilibrium and comfortable binocular vision. No operation was made in this case at any time.

Case II.—Henry R. N., a boy of eleven years. The right eye hyperopic 1D, with vision normal. The left eye hyperopic 5D, and with less than one-tenth vision, but central fixation. The boy received a correcting glass of 5D and practised daily exclusion of the good eye, depending on the amblyopic eye for an increasing period each day. This was continued without intermission from December 31, 1893, to April 18, 1896, when the vision had risen to three-tenths. The boy had learned to shoot with a Flobert rifle, using the amblyopic eye, at glass balls, and had become a good shot. He now began stereoscopic exercises. He is now a bookkeeper, and while the vision of this weaker eye is not four-tenths quite, still he works on and without asthenopic symptoms. He habitually wears lenses correcting the refraction of both eyes.

A most important step in the orthoptic training of the strabismic eye is the effort to revive in the patient a desire for binocular vision and thus recall to the eye its faulty position. The use of the red glass before one eye will, in some cases, provoke diplopia, or a prism with its base up or down before one eye will often cause double vision. It is, however, especially the stereoscope that develops the desire for binocular vision. It is the fusion of the double images in every direction of the axis of vision that is the absolute cure of the strabismus.

It is, perhaps, needless to say that in using the stereoscope we are not concerned alone with the convergence of the eyes, but with the accommodation as well, and as the strabismus itself consists in an alteration of the relations between accommodation and convergence, we must first correct the ametropia.

The stereoscope that I continue to use, and which has been elsewhere described, permits the placing of the half-pictures at any point that may be required to meet the faulty position of the strabismic eye. If this eye has a visual acuity of less than two-tenths, it may well be that but one half-picture at first is seen, or if at all seen, that it soon disappears. With children my practice is to use the familiar cards "Jockey" and "Horse." According to the position of the eye, the horse is perhaps seen, and for an instant its rider. The jockey is, perhaps, on the tail of the horse or on his neck, and the half-pictures must be either approximated or separated to meet the faulty convergence or divergence of the visual axis of the deviating eye. This stereoscopic exercise is to be followed daily, and the actual lateral distance of the half-pictures from the median line noted. Together hand in hand with this exercise the monocular exercise of the amblyopic eye should be continued.

Case III.—Rosamond G., seven years old, strabismus convergens of the right eye. For all distances the inner margin of the cornea of the right eye reached the inner canthus, by fixation of the left eye. With + 3Dc (90°) the vision of the right was less than one-tenth, and central fixation was uncertain. The left eye with + .50Dc (90°) had normal vision. The child was first seen in March, 1899. She received full correction of the refractive error, and her governess was instructed to see that every forenoon and afternoon for a half hour each eye in turn should be bandaged, while the fellow eye was assisted by the correcting lens. This practice was maintained for several months and with great regularity. Between these monocular exercises the little patient wore her spectacles always. In July, 1899, central fixation could be definitely demonstrated, and by Monoyer's tests the vision was two-tenths, but the patient complained that the letters M P could be seen only for a moment and then disappeared. A special card was now made for the stereoscope, on which an L and an I were almost in contact, and with this the patient could secure binocular vision. During the summer the exercises, binocular, were continued, and the patient was encouraged to depend more and more upon the amblyopic eye, playing at cards, games, etc., with the good eye blindfolded. The stereoscopic exercises were continued, and in the autumn she could see properly many of the Kroll and Dahlfeld cards. In the winter of 1899-1900 the vision of the weaker eye had risen to three-tenths, and at that it continues to the present time. The child has had the most varied exercise for this amblyopic eye. She has, for months, for a half hour daily, written sentences at dictation, while the sound eye was bandaged; she has shot with a bow and arrow at a target, using always the weaker eye. The apparent strabismus is not entirely corrected, and it may be that a tenotomy will yet be required, but a useful eye has been secured, and the visual acuity raised by unremitting care.

It will be said that it is difficult to make a patient take any interest in the training of an amblyopic eye when the vision of the other is good and there are no asthenopic symptoms that do not disappear when the refraction is corrected. This may be true, and doubtless in the one-sided amblyopia of hypermetropes of sixty and over we find many who have never had any inconvenience from it. But the cases that I have cited are those of children, and many other similar ones might be adduced. In cases I and III long persistent training, without operative interference, resulted in the one case in a restoration of binocular vision, and in the other in a decided cosmetic and some visual relief.

In his "Manuel de Strabisme" Javal brings forward many such cases. This author, whose views are entitled to the highest respect, says of the amblyopia ex anopsia that he recalls no case of a child under six years of age where central fixation had been sacrificed (p. 239).

If this be true—if there is a period in child life when systematic exercise of the amblyopic eye may result in improved acuity of vision, should we not in all cases see to it that the weak organ be made strong and the infinite advantage of binocular vision be secured?

Laryngeal Perichondritis in a Diabetic Subject.—A case of this rare combination of lesions is reported by Hutchison, the patient being a man of thirty years. Laryngeal symptoms were ushered in by an attack of dyspnœa, dysphagia, pain in the neck, and some stridor to the breathing, while a distinct acetone odor was appreciable in the breath. All that could be seen in the larynx was a large red swelling, running from the back of the arytenoid region to the epiglottis, completely hiding the left cord. The right arytenoid region was considerably swollen, partially hiding the right cord. Externally the laryngeal region was swollen and tender, especially on the left side. The patient died in an attack of dyspnœa. The whole condition developed inside of one week. Syphilis and tubercle could be excluded as the cause of the perichondritis, and it was concluded that, owing to the low tissue vitality, the ordinary pus germs were able to penetrate the laryngeal mucosa and to flourish in the deeper tissues.—*Journal of Laryngology.*

THE TREATMENT OF INTERNAL HEMORRHOIDS.*

By W. DUFF BULLARD, M.D.,
NEW YORK.

So much has been said and written upon the hemorrhoidal disease that I approach the subject with some trepidation. However, as there still seems to be some diversity of opinion among surgeons as to the best method of treatment, my experience of the past five years with the different operations and their results may be of value. I shall not attempt to give an account of the peculiarities of individual cases requiring certain modifications in the technique of the treatment. In such cases the operator must be governed by his common sense and experience.

In my opinion, there are only four well-recognized methods of operative interference worthy of the name. They are the injection method, the Whitehead or American operation, the ligature, and the clamp and cautery. If it were not for the fact that some surgeons still prefer the first and second methods, this paper would never have been written. It is to these surgeons that I would appeal and hope to influence. It is beyond my comprehension why these methods were ever introduced, and it is still more difficult for me to understand why they are employed to-day. Surgeons have had ample time to study results and compile series of cases, and at least every hospital surgeon must have had opportunity of observing for himself serious life-long injuries to the performance of the normal functions of the rectum, resulting from these forms of treatment.

The injection method consists in the passage of a hypodermic needle either into the substance of a hemorrhoidal tumor or the interstitial tissue of the rectum, followed by the injection of some bland, irritating or caustic medicament. Personally, I have had no experience with the injection treatment, and never expect to have so long as there are so many better and more satisfactory methods at our command. The description of the technique of this method, therefore, is necessarily taken from the literature upon the subject, and also from my experience with patients in whom injections have been tried and have failed to accomplish the results desired, the patients having subsequently come into my hands for further treatment.

The patient is placed on the table, either in the dorsal or Syms position, and an examination is made. If internal hemorrhoids are not seen protruding through the anus, an examination is made with the finger and a speculum in the orthodox fashion. The patient is then given a soap-sud enema and told to strain hard and expel it. If the patient has hemorrhoids of any size they will be prolapsed when he returns to the table. If no protrusion of hemorrhoidal tissue occurs, the operator is compelled to administer the injection through a speculum, which is a difficult procedure. The operator now prepares the hypodermic syringe and fills it with the favorite solution. The most popular medicaments for this purpose are carbolic acid in 5 per cent., 10 per cent., or even 50 per cent. solution, fluid extract of hamamelis, ergot, sperm oil, and tincture of iodine, all of which may be employed either alone or combined in various ways. The needle is then inserted into the center of one of the smaller piles, and from five to thirty drops of the solution injected. This causes the patient more or less pain, depending on the strength of the solution used. The operator, judging from his experience of the amount of inflammatory reaction the individual rectum will stand, then ceases the operation for the time or recontinues and injects one or two more hemorrhoids. The prolapsed mass is then replaced in the bowel and the patient told to return in two or three days for further injections. This method seems to be part and parcel of the outfit of charlatans and irregular practitioners of to-day.

Its execution does not require any great amount of surgical training, and will secure in the majority of cases, if cleverly done, temporary benefit, without confining the patient to bed, or the aid of a general anæsthetic or necessitating suspension of business. All of these factors are of the greatest importance to the patient, who cannot see danger ahead. This method, however, is decidedly unsurgical, and its effects in a really troublesome case of hemorrhoids are far from lasting. Furthermore, it is applicable only to certain kinds of hemorrhoids, and is of no value in the thrombotic, œdematous or septic and cutaneous types. Nearly every reputable practitioner, using this form of treatment, has his own technique and injection fluid, while each one claims as his own all the advantages and none of the disadvantages which may accrue to the method. The ultimate object seems to be the same; namely, to produce contraction of the bloodvessels, and excite the formation of adhesions between the hypertrophied mucous membrane and subjacent interstitial tissue.

The cellular spaces existing between the rectal mucous membrane and submucosa are very large and easily ruptured. This can readily be demonstrated by the injection of air through a blow-pipe introduced beneath the mucous membrane of the bile-bearing area. Almost immediately a ring of mucous membrane will bulge at the anus. If the injection is continued, the mucosa will prolapse below the anal margin. The obliteration of these cellular spaces between the mucous and submucous tissue is what is sought for in the injection method. The injection of ten minims of any solution will frequently cause the formation of a small nodule at the margin of the anus. This is always quite painful, and consists of prolapsed mucous membrane, filled with the remnants of ten minims of fluid plus nature's serous effusion, due to irritation. This is spoken of by the "Injectionist" as prolapsed hemorrhoid. Following this irritation a few adhesions between the mucous membrane and the submucosa will occur, and a patient suffering from a few hemorrhoids will no longer be troubled by their prolapse, and in consequence will have no active symptoms of the disease. The continuation of this same process produces well-marked adhesions, which will persist for a varying length of time and thus relieve the patient. If the material injected is not readily absorbed or becomes infected —and no one can tell when this is going to happen; probably in your most important case—a small abscess forms at the anal margin, which causes the patient more pain than he ever experienced from his hemorrhoids. The abscess is either absorbed or opened by the attending surgeon, leaving a granulating wound, which, it is more than likely, results in a superficial fistula, extending from the site of the injection to the anal margin. This is the most frequent untoward result observed. It is not dangerous to life, but it causes much inconvenience and pain and usually calls for surgical interference.

It is difficult to explain these things to a patient who is told that he will suffer no pain from the treatment, unless he can be convinced that he is suffering from a complication of strangulated hemorrhoids, to which the charlatans usually attribute every disagreeable symptom incident to their treatment. If the injection is made a little too

---

*Read before the New York County Medical Association.

Should the inflammation spread at all, a very illness with constitutional symptoms, high temperature, anxious face, and failure to [illegible] to ensue.

If it be just above, perirectal cellulitis or periproctitis may result. The only other complication which to my mind requires consideration here is that condition in which the injection material used causes considerable inflammatory reaction and a slough of the mucous membrane, followed by the formation of an ulcer. Time will not permit me to discuss all the details of such a case, but anything from three or four bloody discharges in twenty-four hours to an unyielding stricture may result.

Some authorities claim that pyæmia, embolism, and even death have followed the use of injections. The literature at my command, however, does not show any well-authenticated case of death from these causes.

As usually understood, the Whitehead operation, briefly stated, consists of the denudation of the pile-bearing area of the rectum. This operation begins by an incision just inside of the margin of the anus. The mucous membrane is dissected up for an inch and a half to two inches inside the bowel. The mucous membrane then hangs loosely in the bowel as a tube. The distal end is then seized with a clamp and pulled down as far as possible. Two inches of this freed mucous membrane is then excised.

This amputated membrane is supposed to contain all the so-called "pile-bearing area" and, of course, all the other structures contained in the lower two inches of the rectal mucous membrane. The free end of the mucous membrane remaining in the rectum is then loosened at the edges and sutured to the original line of incision. In other words, a complete circle of mucous membrane is removed from the bowel, and its place is taken by drawing down the mucous membrane from a higher plane.

It can readily be seen that the proper performance of such an operation requires considerable surgical training and the exercise of great care. Indeed, it is no simple matter to dissect off mucous membrane from the underlying tissues, especially if engorged and bleeding. As an illustration I will mention a case in my own practice:

About eighteen months ago a patient, who had been operated upon for piles by one of New York's specialists, called at my office. A Whitehead operation had evidently been attempted, but in its performance the operator had apparently cut out and discarded the external sphincter as "pile-bearing area" and part of the mucous membrane. Instead of occasional attacks of painful piles now, the patient suffered from incontinence of fæces, and was doomed to wear protectors and to soil himself at all times and in all places. This patient seemed to feel that the remedy was worse than the disease.

Of course, no thoroughly competent rectal surgeon could quite get such a result as that. But no matter how competent the operator may be, if he persist in doing the Whitehead operation he must rely on securing primary union in the bowel, which is a difficult thing to do under the most favorable circumstances. The rectum is a difficult organ to sterilize and to keep so for any length of time. The mucous membrane, which has been drawn down and stitched to the anus, must be in a more or less constant state of tension. A suture is likely to pull out during a paroxysm of coughing, vomiting, or at defecation. The result is an ulcer.

If all the sutures pull out, as occasionally occurs, it is extremely doubtful if a stricture of the anus can be prevented. Such a case was seen by me in consultation a short time ago.

The patient had been operated upon one week previously. The lower two inches of the bowel was completely denuded of mucous membrane. The mucous membrane that had been stretched down had curled up at the top of the wound and glued itself by inflammatory products. The cause of failure in this case seemed to be that the patient had vomited very forcibly after ether and the catgut sutures had become softened, loosened, and melted by the wet dressing that had been applied. Here I gave an unfavorable prognosis, and advised a second operation with sutures preferably of silk. It was impossible for me to trace the case afterwards, but I am convinced that, in spite of any further operation, the patient probably has had stricture at the anus, or at least has lost control of the sphincter from the induration of the tissues due to the extensive cicatrix. The probability of securing primary union in such a case is very much lessened. The freshening of such a wound in the hope of primary union is a difficult surgical feat, and even the most expert is liable to include in the freshening more than mere granulating area.

My observations of a number of other cases in addition to the two striking instances just referred to make me marvel why any surgeon would today venture to do this operation. Fortunately, I believe it is done once to-day where it was done ten times some years ago.

To-day the ligature operation, sometimes referred to as Allingham's operation, is perhaps the favorite mode of treatment for internal hemorrhoids. It is, no doubt, more popular in England than in America. The technique preferred is as follows: The bowels of the patient are kept loose for a day or two previous to the operation. The patient is anæsthetized and placed on the table in the dorsal position, the legs being confined and held out of the way by a Clover's crutch. When anæsthesia is complete the operator should insert the index finger of each hand into the anus and separate them slowly and carefully until the sphincters are thoroughly dilated and temporarily paralyzed. If any fecal matter remains in the bowel, this is washed away with a weak solution of bichloride. A wire speculum is then inserted, separating the walls of the bowel, and allowing the hemorrhoids to prolapse into the lumen of the speculum.

The operator should then decide the extent of the disease, and which hemorrhoid it is advisable to ligature first. He should be governed in the matter by a desire to avoid too much cicatrix later, and by a desire not to have the field of operation covered with blood. In other words he should ligate first the piles on the posterior wall and close to the anus. If the base is too large and close to the cutaneous margin, it is wise to cut the hemorrhoid loose from the skin and the submucous tissue with a pair of scissors. This cutting should be made parallel to the longitudinal axis of the gut. The remaining part of the hemorrhoid, now mainly vessels and mucous membrane, should be tied off with a strong ligature. Silk is preferable, although catgut which is not absorbable for at least two weeks, may be used. This ligature is now tied, and the hemorrhoid excised. Care should be taken not to cut the hemorrhoid so close to the line of ligature that, when there is no longer tension on the mucous membrane, it will slip. Serious hemorrhage might result. Several deaths have been reported from such an occurrence. After all the hemorrhoids have been tied and removed in like manner, the speculum is again inserted to see if any have been overlooked. Any cutaneous tags should be snipped off and a tight compress of gauze, covered with vaseline, applied.

The patient is kept in bed until the ligatures come away, which is usually in about a week. The bowels should not be allowed to move for two or three days. They can be controlled by the administration of a bismuth and morphine powder given a few hours before the operation.

It is well to inform the patient that he will have some pain for a few days following, and also with the first movement, a little blood. This can be avoided to a certain extent by the administration of a licorice powder on the morning of the third day, and when the bowels are inclined to move a soap-sud enema.

The clamp and cautery operation was first introduced by Cusack of Dublin, then was adopted by Smith of London, and Kelsey of New York.

After dilatation of the sphincter, as described in the ligature operation, the hemorrhoid is drawn down with a double tenaculum and its base seized with the clamp. The hemorrhoid is then cut off with a pair of strong scissors, and the stump burnt with the Paquelin cautery. The grasp of the clamp is then loosened, and the eschared mucous membrane is allowed to slip slowly back into the rectum. Care should be exercised not to cut the hemorrhoid off too close to the edge of the clamp, but to leave enough tissue to burn thoroughly and make a thick eschar. The clamp should always be adjusted, so that the eschar, when released, lies in the longitudinal axis of the bowel. Any number of grasps of the clamp may be made without danger, if this be observed, but three are generally sufficient if the amount of tissue in each grasp is carefully and intelligently regulated. When this has been accomplished a T-bandage is applied, and the patient is returned to bed. In comparison to the ligature, this operation possesses, to my mind, a few advantages. In the ligature, the irritation from the sutures generally cause some vesica tenesmus, which has to be relieved by catheterization. The pain in the ligature operation is somewhat more constant and severe. It persists until the ligatures have all sloughed off. The convalescence is more prolonged than in the clamp and cautery; the average time in bed being about nine days, while in the clamp the patients are repeatedly up and around on the fourth day.

The ligatures may be caught by a lump of fæces and torn off, considerable hemorrhage resulting, while I have never seen the sloughs from the clamp and cautery give any secondary complication. As far as a cure of internal hemorrhoids is concerned, either operation, when properly performed, will produce a satisfactory result. My own feeling in the matter is that the ligature operation is a little more to be followed by recurrence than is the clamp and cautery operation. I have never seen a recrudescence after the clamp and cautery operation. However, if my cautery should give out during an operation, I should feel perfectly safe in completing the operation by the means of the ligature. In conclusion:

The injection and Whitehead methods should be abandoned. The only value the injection method can possibly possess is its applicability in the case of dangerously ill patients, to whom an anæsthetic cannot be administered. The risk, however, is too great, and it is, therefore, safer for the physician to adopt one of the palliative methods, with which all of us are so familiar, such as suppositories, poultices, ice cloths and laxatives. The Whitehead method has no advantages. I am at present working upon an operation which can be performed in the office upon those individuals who refuse or are unable to take an anæsthetic. Thus far, however, I have been able to make use of it in but a small number of cases, and I am, therefore, unprepared to give it to the profession. When I have convinced myself that the operation is in every way superior to the injection methods for office treatment, I will venture to describe it in detail.

The ligature and the clamp and cautery operations are the proper procedures to employ, the latter possessing the advantage of a more speedy and painless cure and less liability to complications.

IS THE MIND AN ENTITY?

By H. H. STONER, M.D.,
HIGHMORE, S. D.

This question has been suggested to me by a perusal of Dr. J. Allen Gilbert's article, "The Psychic Half," in the Medical Record for December 7, 1901, in which he takes the affirmative side of the question. It is not my intention to offer a criticism upon Dr. Gilbert's essay; I only desire to present the other side of the question.

The present state of our knowledge will not admit of a demonstrable solution of the problem. Whether the future will solve it remains yet to be seen. The best we can do at this time is to take the data at our command, hold them up in the broad light of reason, and, looking at them from every possible standpoint, arrive at our conclusions.

Is mind an entity? To get at the essence of this query we must go to the very foundation of mental phenomena and ask, Is consciousness an entity? Every one must agree that consciousness is the root of all mental acts, and that from it arise all the manifold phenomena of the mind. To undertake to define consciousness would be to undertake to tell the neural process by which it is brought into existence. Any one who, in the present state of our knowledge, tries to define this element of mentality must resort to tautology, with the result that, in the end, he has not defined it at all. Thus, says one, consciousness is "the power by which the mind knows its own states and actions." This is equivalent to saying that consciousness is consciousness, which tells us nothing. The impingement of a stimulus upon the psychical neurones, the instigation of sensation, and the arousal of consciousness are so closely related, so intimately blended, if we may not say fused, that it is difficult to determine just what relations they bear to each other in the manifestation of mental states. Thus a stimulus falls upon the psychical elements of the brain, which results in a sensation; closely following, and almost simultaneous with it, there arises a consciousness of the sensation. Just what mediates between the sensation and the manifestation of consciousness we cannot tell. What neural process takes place in the interim we do not know; but that some physical process does take place at this time within the cells of the psychical neurones by which consciousness is evolved, and we become cognizant that a stimulus has upset the quiescent balance of the neural relations seems so rational, so positive, that, to my mind, at least, it does not admit of question. How much more reasonable seems such a theory when compared with one which states that immediately upon the reception of a sensation there steps in an entity, called mind, spirit, soul, which asserts that "I know"! Can it be that sensation is the result of a physical process, and consciousness is not? Nothing is plainer than that sensation arises in consequence of the disturbance of the psychical elements incident to the impact of a stimulus which has been transmitted to the brain over the afferent nerves. Sensation is certainly a positive phenomenon, and if one of the phenomena of psychic life can be called into being by the action of a physical force, is it not reasonable to suppose that all may be so generated?

In dealing with the psycho-physical side of the question, then, it may be assumed that as a result of the impingement of a stimulus upon the peripheral end-organs, sensation has its birth; that coincident with, or immediately following, sensation, in some inexplicable manner, consciousness arises; that the recurrence of identical conscious states constitutes memory; and that reason arises as the result of the comparison of remembered conscious states. These phenomena all have their origin either directly or indirectly in a physical stimulus. Sensation is dependent upon it; consciousness cannot arise except it be called up by the influence of an external stimulus; memory would be a thing of naught were there not something to suggest it; reason could not be exercised in the absence of a remembered conscious state. Take away the stimuli of our environment, and of what use would be the organ of mind? If every avenue over which impulses travel to the brain could be effectually blocked, so that not the slightest thrill could gain access into the cortical precincts, how long, think you, would mental processes continue? The present thought might go on a few seconds, but only a few, for no sooner would the normal stimuli of the psychical cells be withdrawn than the processes of all the cerebral neurones would fall out of functional relation with each other, and the brain would pass into an eternal dreamless sleep.

Because we cannot tell just what physiological process takes place within the psychical cells at the moment when consciousness emerges as a necessary product from sensation, is no reason for asserting that it is not essentially a physiological product. It does not clarify the matter one whit by saying that consciousness is an entity, a reality, a substance without spatial relations, and that it has an existence outside the boundaries of the brain.

Mind and body are related because neural activity and the bodily functions are interdependent. All the organs of life are presided over by the nervous system, and these organs in turn supply the motive force of the nervous system. It is true that the great majority of stimuli which play back and forth between the nervous system and the bodily tissues by way of the sympathetic nervous system do not reach the psychical apparatus of the brain at all, and, consequently, do not give rise to conscious states. They are what may be called reflex nervous phenomena. When these stimuli become so intense that they overflow their boundaries, or when the reflex paths become incompetent to transmit the volume of stimuli, a portion is transmitted to the cerebrospinal system, and arriving in the psychical precincts gives rise to a peculiar sensation which we are pleased to call an emotional state. And, vice versa, when mental impressions arise of such intensity as to overtax the carrying capacity of the cerebrospinal system of nerves the excess passes off into the sympathetic nervous system, upsetting the normal balance of tissue metabolism which upon being retransmitted to the brain is there again interpreted as an emotional feeling. In this way, and in this way only, are mind and body related. Emotional feelings and the esthetic sense arise in consequence of stimuli emanating from the tissues of the body. The stimuli which call into being these peculiar sensations are carried in over the sympathetic nervous system. The character of a sensation depends upon the quality of the stimulus which calls it into existence. Thus ethereal vibration produces the sensation of sight, atmospheric vibration that of hearing, contact that of touch, and disturbed metabolic processes that of emotion. The relation between the sympathetic functions and the manifestation of emotional states is well exemplified in the blush of shame, the pallor of fear, and the flush of anger. The phenomena are so clearly dependent upon metabolic stimuli for their manifestation that it seems like a waste of words to argue further upon the question. If we are ever to understand the physiology of the mind, psychology and theology must be divorced. If we locate the seat of reason in the brain and assign to it mental attributes, we erect a barrier which says to physiological psychology, "Thus far shalt thou go and no further." There is nothing in physiology more certain than that the brain is the organ of mind, and as the liver secretes bile, the muscles produce energy, so do the myriad millions of psychical cells of the brain generate thought.

Are the behests of the will called upon for decision, and are we strictly responsible for our acts? If the mind is a creature of circumstances, depending upon the chance stimuli which find their way into the brain, the answer must be "No." If under certain conditions I perform an act to-day, to-morrow, if every condition be exactly repeated, I would perform the same act and in precisely the same manner. Mind you, I say every condition; this includes every environment and mental state. Under such circumstances I would be driven blindly into a repetition of the act absolutely without recourse. But if some passing stimulus, gaining access to the brain, should divert my train of thought in the least possible manner, then my conduct would change proportionately. I would not dispense with courts of justice, nor withhold punishment for the commission of crime, for the fear of retributive vengeance in the mind of the [illegible] criminal may serve as the stimulus to divert his mind into better channels.

To the medical man the mind must be looked upon as being a purely physiological product—a product capable of being warped and bent by its environments. A mind made of such material may be influenced and diverted into channels of mental and bodily health, but a mind whose essence is distinct and separate from the bodily functions could not be reached by human means.

Hemorrhages from the Ear in Hemophilia.—A case of this nature is reported by T. Smith occurring in a boy of two and a half years, with [illegible] and fever. Inflammation of the left middle ear was made out, and paracentesis was done. The child did well for about a week, when blood began to flow from the ear, though after the latter had been syringed no cause for the bleeding could be discovered. The bleeding continued at intervals for eight days in spite of plugging the meatus, and a fatal result was feared, but on the ninth day the bleeding ceased and did not return. The family history seemed to indicate hemophilia. Throughout the whole duration of the hemorrhage no blood had leaked into the Eustachian tube. On the sixth day a small blood-clot was removed from the auditory meatus in order to investigate it microscopically. The preparation showed [illegible] embedded in mucus. After the cessation of the hemorrhage, improvement speedily set in. The ear discharge entirely ceased, and the hole in the tympanic membrane healed within four days. The child became quiet and slept well. In three weeks the membrana tympani appeared normal and the child was perfectly well.—*Medical Press and Circular.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 29, 1902.

GOVERNMENTAL CONTROL OF THERAPEUTIC SERUMS, VACCINE, ETC.

Public Health Reports, January 17, contains an account, prepared, under the direction of the Surgeon-General, by Past-Assistant-Surgeon H. D. Geddings, U. S. M. H. S., Acting Director of the Hygienic Laboratory of four of the principal European countries relative to the preparation, sale, and distribution of therapeutic serums and other analagous products.

The laws in France are fairly stringent, providing that attenuated viruses, therapeutic serums, modified toxins and analagous products, applicable to the prophylaxis and therapeusis of contagious diseases, and injectable substances of organic origin, of undefined chemical composition, applicable to the treatment of acute or chronic affections, shall not be marketed under an actual or trade name until they shall have been, in point of view of manufacture and origin, the recipient of a governmental authorization, rendered according to the judgment of the consulting committee of the Council of Hygiene of France, and of the Academy of Medicine. These products will be granted a temporary or revocable license only, and shall be submitted to the inspection by a commission appointed by a minister having competent authority.

Regulations are also in force providing for the mode of issue of such products, but animal or humanized vaccine virus is not included in the regulations.

In the German Empire diphtheria antitoxin is the only one of the serums which is governed by the trade ordinance of the country.

The restrictions placed by the Government of Italy upon the production and sale of therapeutic serums are more comprehensive and thorough than in any country of the world. The law provides that no one shall, without consent of the Minister of the Interior, prepare for sale (*a*) vaccine; (*b*) virus; (*c*) therapeutic serums; and (*d*) toxins, antitoxins, and other similar preparations. The conditions for this consent and the special instructions in regard to the preparation and the sale to be determined by the Government after hearings from the Council of Health.

The Russian Commission for the Prevention of the Introduction of the Plague, at its sitting of May 3, left the preparation of anti-pest serum with bacteriological institutions which have given the necessary guarantees, on condition (1) That no money shall be paid to the Crown to such establishments; (2) That no obstacles shall be placed by the local authorities in the way of the preparation of these serums; (3) That the serum shall be prepared harmlessly—that is to say, by means of dead microorganisms or toxins, and not by means of living cultures; (4) That the serum prepared shall, before being sent from the Imperial Institute of Experimental Medicine, be tested; and (5) That the Commission reserves the right of disposal of the serums to the places and institutions which have the most need of it.

It will be noticed that no mention is made of any laws on the subject in Great Britain, and that, with the exception of Italy, no country controls the manufacture or sale of vaccine.

Of late, owing chiefly to the accidents which have occurred recently in this country from the use of diphtheria antitoxin and vaccine virus, there has been a movement in favor of Government control of such products. This proposition is not only highly proper under present circumstances, but absolutely imperative. But here governmental control of commercial products should stop. No municipal or State board has any right to manufacture such products for sale, and thus compete with private manufacturers. There is no objection to any health board making virus and antitoxins for its own use among the poor and for free distribution in the interests of public health; but beyond this it should never go.

No government has the right, morally, legally, or commercially, to enter into any business for pecuniary profit. There is no possible excuse for such a course, no matter how charitably it may be viewed on the score of guaranteed purity of product or its cheapness to consumers. The purity of any chemical product can be vouched for by proper inspection, but there is no good reason why any health board should enter the list of traders in such articles, and openly, under cover of official sanction, advertise its wares in the open market. Such a course would imply that all chemists outside of the board were either incompetent to make these articles or professedly dishonest in their methods. The advantage is an unfair one in every respect, as it is well known that the products in question are made with the greatest care by several large firms, and their purity is never questioned. In fact, with many of them the facilities for manufacture are so far superior to those of ordinary health boards as to be beyond the need of contrary argument.

There is no excuse, either, that the funds from the sale of these health-board serums are necessary for progressive bacteriological work. All appropriations for the latter should come from public funds, and not even indirectly from the legitimate profits of firms who honestly strive to do business on fair business principles.

We notice incidentally that the *Drug Reporter* of this city has taken up the subject from the same point of view, and has circulated a petition, which is to be presented to Mayor Low for his action in the matter. Our esteemed contemporary takes a very proper view of the question, and forcibly urges the necessity of forbidding the sale of serums and virus by the Health Department. It very truly and pertinently says that the present practice "is contrary to the principles of political science, unjust to mercantile interests, and exercises a disturbing influence on commerce."

In other words, it is the Government's business to inspect products, but never to manufacture them for sale. A municipal laboratory is not a shop.

CONGRESS AND PURE-FOOD LEGISLATION.

A very excellent bill now before Congress, regulating and restricting the sale of adulterated food-stuffs and providing penalties for fraud in connection therewith, is of much interest to the medical profession by reason of the character of the evidence given by witnesses before the Congressional committees with respect to the material and methods commonly employed in the preparation of a large number of articles of food. In their efforts to meet trade competition without going into detail, it appears that there is scarcely a food preparation in ordinary use which is not subject to imitation, adulteration, and substitution by the unscrupulous. It comes also as a shock to learn that a number of the larger and supposedly trustworthy business firms are not among the least sinners in this respect, and that they are placing on the market preparations which are either directly deleterious or are intended to deceive the purchaser into believing that he is securing an article of superior quality. Of course these adulterations are particularly intended for a cheaper class of trade, and thus it is the laboring classes, whose first requisite is an abundance of nutritious food of good character, who are the chief victims of commercial greed, and who especially require the protective legislation proposed.

Naturally, the firms whose fraudulent money-making schemes are threatened are bitterly opposed to the enactment of pure-food legislation, and are doing everything they can to prevent the proposed reforms. For several weeks the Congressional Committee rooms have been crowded with their representatives in the effort to convince Congress that the public is the lawful prey of the individual and that the general health and welfare is quite subordinate to personal commercial ends. One manufacturer of food-stuffs complained bitterly to the committee because of the interference with his "business interests" resulting from legislation in a certain State requiring him to label as imitation the composition "jellies" prepared by him. He stated that his sales had fallen, in respect to these "jellies," from a thousand buckets to twenty buckets a day, as a result of this legislation. He admitted, on further inquiry, that his "currant jelly" was made from apple cores and parings, or other fruit refuse, boiled to a pulp, stiffened with starch, sweetened with glucose, colored with an aniline dye, and artificially flavored. He did not say, however, and which is probably the case, that his delectable article of food had been kept from putrefactive changes by chemical food preservatives, such as salicylic acid or the sulphites. He could see no objection to labeling his preparation as pure currant jelly and putting it on the market to compete with a pure article of the latter. Other witnesses contended that the adulterated preparations sold by them were not injurious to health, but they were forced to admit that these were sold under fraudulent brands denoting that they were first-class goods. Misleading labels were found to be a very common means of evading existing laws, even though complying with the letter of these laws.

All the manufacturers represented before the committee united to vigorously oppose the imposition of any penalty for infringement of the proposed pure-food laws. If such legislation was to be enacted they strongly objected to any provisions by which it might be made effective and offenders in this respect punished. By their attitude they showed exactly how far they would observe such laws in the absence of penalties compelling them to do so and also the value they attach to the public interests as compared with their private gain.

These men plainly menace the welfare of the communities upon which they prey. They are making a strong fight to perpetuate present conditions and prevent urgently needed reforms. They are well supplied with funds, the trade in which they are engaged shows them to be thoroughly unscrupulous, and their cry of "injury to business interests" is one which appeals strongly to Congress. They are on the ground to prevent effective pure-food legislation and are united to form a political power the strength of which is not to be underestimated. In their efforts to exploit the public they can be best opposed by their own political methods, and to this end all health officers and those interested in public hygiene should urge upon their Congressional representatives the necessity for pure-food legislation based upon the admirable bill introduced into the House by Mr. Hepburn. This is an instance where a united medical profession should be utilized as a political lever to force the enactment of legislation favorably affecting the public health and welfare. The importance of uniting the medical men of this country into an effective political unit, to be used for non-partisan ends in the interest of humanity and medical science cannot be too strongly emphasized.

DENTISTRY AS A SPECIALTY OF MEDICINE.

Dr. O. N. Heise, of Cincinnati, read before the Cincinnati Odontological Society a paper dealing with the above subject, which, from one point of view, treats of the situation clearly and frankly.

Many dentists have been for long impressed with the idea that as their profession now requires a scientific training, so should the entrance examinations and the course throughout be raised to a much higher standard than at present prevails.

The dental student needs to have a fair knowledge of anatomy, physiology, pathology, materia medica, chemistry, and bacteriology, and especially of the first three. Thus, looked at from this standpoint, there would seem to be good reasons for conducting the training of the medical and dental student upon almost identical lines and in the same class.

Dr. Heise was very outspoken in the expression of his ideas on the matter, and spoke in part as follows: "That the dentist should have a thorough medical training is, in my mind, a settled fact, and it seems to be it cannot be obtained in the average dental college. Why should not the student acquire his knowledge of medicine at the fountain head, from men who have studied these branches more thoroughly than any dentist would or has the opportunity to do? Where, also, he can have the advantage of practical laboratory courses of instruction in all the various branches, which the dental college does not give. Again, the hospital instruction and clinical work are of paramount importance in giving broader ideas than he can get from spending all his time in the dental clinic. The chair of oral surgery gives the dental student an opportunity to witness operations other than the strictly dental ones, but he should see more than a few such operations during the year. He should obtain a knowledge of general medicine not from books alone, but by clinical instruction as well.

One of the strongest points brought forward by Dr. Heise in support of the view that the dental student should have a fairly thorough medical training is that the administration of anæsthetics, the injection of cocaine, etc., as ordinarily done by dentists, is likely to bring discredit upon the profession. Patients are given nitrous oxide gas when the dentist has no idea of their general condition. In fact, is the average dentist equipped to ascertain, even in a general way, the condition of the heart, lungs, kidneys, etc., and in case of any serious trouble during the administration, is he qualified to take care of the patient?

In the discussion that followed the reading of Dr. Heise's paper some of his professional brethren voiced their agreement to, while others dissented entirely from, his views.

Those who were of the contrary opinion founded their principal objections upon the belief that this broadening of the dentist's education would tend to lessen his digital skill and dexterity of manipulation—in short, the greater theoretical knowledge that he gained would be more than counterbalanced by his lessened expertness in the practical work of the profession.

Some, too, argued that the dental colleges of the day afford the same advantages to the student in histology, pathology, bacteriology, and physiology as do the medical schools.

The honors of the debate would appear to have fallen to Dr. Heise, and his contention—that it is to the disadvantage of dentistry that it was ever divorced from the medical profession, for it would have been further advanced as a science and have been more efficient in many ways than it is to-day if that separation had never taken place—is based on sound reasoning.

A New Work of Fiction by Dr. Sprigge of London.

Dr. Squire Sprigge, chief of the editorial staff of the London *Lancet*, author of "The Life of Thomas Wakley," and who has recently edited the autobiography of his friend, the late Sir Walter Besant, now appearing, is just about to bring out a novel entitled "An Industrious Chevalier." This work is very highly spoken of by the reviewers on the other side, and is the history, told in a series of episodes, of a gentleman who has been compelled, by the force of circumstances, to prey upon his fellow creatures. The book, which may really be termed a collection of studies in criminology, is highly diverting and ingenious, while the style is chaste, forcible, elegant, and pointed. Dr. Sprigge's long training in literary work shows itself in the truly artistic finish of his present effort, and ranks him among the many medical men who have adorned fiction with realistic representations and dramatic situations. Doctors as a class see life in all its forms, and when capable of delineating it, are always sure of an appreciative audience.

One of the Defects in Lunacy Bill No. 368.

Lunacy Bill No. 368, which has recently passed, and received the approval of the Governor, contemplates some radical changes in the Manhattan State Hospital, on Ward's Island, which should not go unquestioned. The two departments of this institution are consolidated, thereby displacing one or other of the two medical superintendents, and placing four thousand patients under the supervision of one medical officer. The proposition is an absurd one on its face, and calls for prompt modification. A supplementary bill should be introduced restoring former conditions of administration. No medical superintendent should be expected to look after more than a thousand patients. On Ward's Island this number was doubled under the old plan, and now an apparent improvement is sought by quadrupling the duties of supervision. Surely this is reform with a vengeance. Where does improvement of administration manifest itself with such slack provision for so large a class of helpless sufferers?

Filters for French Army.

If troops on the march, or in camp, could be supplied with pure water, the propagation and spread of typhoid fever would be largely prevented. Filters are the only means, at present, by which this object can be even partly attained, and none of those in use approach perfection.

The question of easy transportation of such apparatus is important for troops on the march, and it has been found that no filter at present invented combines lightness, efficiency in purifying water, and celerity in the process.

During the past year, according to a statement in the New York *Sun*, March 16, a new model of the Pasteur-Chamberland filter has been introduced into the French army, and special instructions for its care and management have been issued.

The candle of unglazed porcelain is enclosed in a metallic tube, the latter being screwed at top to the water spigot. In this way the necessary water pressure for rapid filtration is obtained, provided that pressure corresponds to a height of column of about forty inches. Otherwise the proper pressure is obtained by means of so-called accumulators, which are cylindrical vessels of sheet iron, capable of withstanding a pressure of three atmospheres, in which the required pressure on the surface of the water is produced by means of an air pump.

The experiments at Versailles show that with a pressure of two atmospheres, even with very impure water, a single candle will furnish twenty-four litres of pure water a day, and will, therefore, be sufficient for seven men.

Such filters possess defects, as do all up to the present time brought out, which render them more or less useless for troops constantly on the march, but at the same time they might prove of value to soldiers stationed at camps or posts where the water supply is unsatisfactory.

The Sale of Quinine in Italy.

The Government of Italy is distinctly paternal, and looks after the interests of its subjects, as regards their bodily welfare, with untiring zeal—not, however, unmixed with pecuniary considerations.

Dr. J. M. Eager, Past-Assistant Surgeon U. S. M. H. S., reports from Naples that there is at present an interesting project of law before the Italian Parliament to give the Government control of the sale of quinine in the kingdom. The design has hygienic bearings. One of the most noticeable street signs in Italian cities is that of "Salt and Tobacco." The sign, carrying also the Government arms, is placed above the doors of shops where the commercial forms of salt and tobacco are sold at retail. At restaurants, when a customer wishes to buy cigars or cigarettes, he must send a messenger to a neighboring official store. A tray containing an assortment of these articles is brought in by an agent. A slight advance in the established price is customarily charged when the goods are dispensed outside the ordinary place of sale. Now, it is proposed to include quinine with tobacco and salt, and should the project become law, as seems probable, it will not be possible to buy the drug elsewhere than at the official dispensaries.

There has been of late a considerable propaganda in the journals, both medical and lay, impressing the prophylactic value of cinchona derivatives in malarial sections. The desolation which has for many years past spread itself over large territories otherwise productive, but notably malarious, has given popular interest to all measures designed to restore to prosperity the afflicted regions. The designs to restore the Roman Campana from the utter waste that has reigned there for centuries are cases in point.

Dr. Kagan refers to the measures of railroad hygiene that have been enforced on lines running through the paludal portions of Italy, and at stations situated in places rendered almost uninhabitable by malaria, and says: "The regulations of the Italian railroads, which are owned by the Government, require all employees exposed to malaria to take quinine at intervals. The same practice is insisted upon in other public services similarly exposed, while it is proposed to distribute quinine gratuitously in dangerous districts. . . . Thus the spread of malaria is in, a degree, checked."

The public control of quinine, aside from assuring freedom from adulteration, is likely to be a considerable source of revenue, because of the fact that in many parts of Italy quinine is as great a necessity as its proposed commercial associate salt, and quite as much in habitual use as tobacco. There is no excuse, however, on the mere pretense of preventing adulterations for the Government to compete with its own merchants in the sale of these products.

CRIME AND EDUCATION.

Education is, perhaps, the most prominent factor in the suppression of crime. The most highly cultured and intelligent nations have less crime than those which occupy a low position in the scale of civilization. The London *Spectator*, of a recent date, has an article on the above subject, in which it says:

"The ignorant races are by no means innocent races. Life and property are safer in Scotland than in Sicily, and though race and creed may be, in part, the causes, still the latter, at least, must be one of the results of comparative intelligence. Crime, more especially violent crime, seems, on the whole, to diminish with the spread of education, though it must be admitted that in some countries, especially France, there are ugly breaks in the completeness of the evidence. The stupid are often cunning, and there is in the ignorant a disposition toward violence, which the late Mr. Hutton, a keen observer of mental peculiarities, always traced to a consciousness of mental weakness, and its resultant, a wish to manifest strength in some direction, and so preserve self-respect.

"The educated are naturally better aware of consequences, and are, simply because they have been trained, less liable to be carried away by those fierce waves of excitement, the causes of which are still not completely traced. The drunken rough is more disposed toward outrage than the drunken gentleman, because the latter retains more completely some relics of intelligence. The evidence of those engaged in education is, we believe, nearly unbroken in the same direction."

In this country the truth of these remarks is being constantly demonstrated. Deeds of unbridled violence occur more often in the Southern States than elsewhere in America. It has been recently shown that illiteracy is more common not only among the negro population of that section of the continent, but also among the whites, than in any other portion of the United States. Race and climate have an important bearing on the matter, but it would seem that these sink into relative insignificance beside that of education. Ignorance does not mean innocence, but on the contrary, evidence goes to show that where ignorance predominates there will vice and crime flourish exceedingly.

ANNUAL REPORT OF THE BOARD OF HEALTH OF NEW JERSEY

The twenty-fourth annual report of the New Jersey Board of Health has recently been issued, and contains, as usual, a large amount of matter of much interest.

During the statistical year ending June 30, 1900, the number of births reported and recorded in New Jersey was 32,270. The number of deaths recorded in the same period was 31,474, and the population of the State, by the United States Census of 1900, is 1,883,669. The death rate for the year was, therefore, 16.70 per 1,000.

The infant mortality was greatly reduced. This reduction, it is believed, was largely due to the partial sterilization of milk, which has, within the past six years, been commonly practised among the more intelligent classes throughout the State.

The death rate from pulmonary tuberculosis has been lower during the past five years than at any previous period since the records of the Bureau were begun in 1879. Typhoid fever caused 356 deaths. In the previous year the deaths from this disease numbered 486.

During the twenty-two years, 1879–1900, cancer caused 13,991 deaths in New Jersey, an average of 635 each year. The number of deaths from this disease for the year ending June 30, 1900, was 921, this number being 25 less than during the previous year, but being 286 in excess of the average for the whole period during which records have been made by the Bureau. Malarial fevers have shown a decided diminution, while smallpox, although of a decidedly mild type, has been somewhat on the increase.

State laws securing the better enforcement of maritime quarantine have been passed with good results. State laws relating to contagious and infectious disease, including medical inspection of schools, and the provision of isolation hospitals have also been passed, and strictly enforced.

The careful inspection of public water supplies has been enforced, and, on the whole, it may be said that New Jersey has no reason to complain of her water, either as regards quality or quantity.

In the report of the bacteriologist, it is stated that the diagnostic work has consisted chiefly in the examination of specimens from suspected cases of the following diseases: Diphtheria, tuberculosis, typhoid fever, gonorrhœa, and malaria. During the year 2,380 such specimens were examined.

In 1900 several bills relating to public health were passed in the State Senate and Assembly, and there is every evidence that the Board of Health of New Jersey is ever on the alert to propose and execute any measure which might tend to prevent disease, and to preserve the health of the inhabitants of the State.

News of the Week.

The Tri-State Medical Society of Iowa, Illinois, and Missouri will hold its tenth annual meeting at the Great Northern Hotel, Chicago, April 3 and 4, 1902. All members of the regular medical profession of Iowa, Illinois, and Missouri in affiliation with the aims and practices of the American Medical Association are invited to attend the meeting.

McKinley's Doctors' Bills.—The bills for attendance on President McKinley have been formally presented. The sum total is said to be in the neighborhood of $100,000. Senator Hanna will present the bills to Congress for payment.

Quarantining Against Consumption in Colorado.—The members of the Colorado State Board of Health are seriously concerned over the fact that repeated statements have been made, and emphasized in a prominent medical journal, that Colorado has gravely considered quarantining against consumptives. The State Board of Health, therefore, wish to make a decided and categorical public denial of such assertion, and have sent to us a statement, signed by the medical members of the Board, repudiating the idea that any action with this object in view has been contemplated by the Board.

Annual Dinner of Eastern Medical Society.—The Eastern Medical Society of New York City held its annual dinner at the Broadway Central Hotel, Saturday evening, March 22. The attendance was the largest in the Society's history. After the dinner was served the following toasts were responded to:—"Man and Mind," by Rev. Dr G. Gottheil; "Our Specialties," by Dr. Emil Gruening; "Our Hospitals," by Dr. Arpad G. Gerster; "Our Sister Societies," by Dr. Parker Syms; "Our Own Society," by Dr. R. Abrahams. Dr. Wm. S. Gottheil acted as toastmaster. The dinner was concluded by a dance.

To Prevent the Introduction of Yellow Fever into Havana, with its subsequent development and spread, an order has recently been issued by the Military Governor, as follows:

"All persons non-immune to yellow fever coming to the city of Havana from places infected with yellow fever shall report at such time and place as directed by the chief sanitary officer of the city of Havana. The chief sanitary officer shall be the judge as to immunity and infection, and shall serve proper notice upon persons concerned. Violations of this order shall be punished by a fine of not less than $5.00, nor more than $50.00, United States currency, or by imprisonment of from one to ten days."

The provisions of this order will enable the sanitary officer to keep all possibly infected strangers under observation during the yellow fever incubation period, and to take prompt measures to stamp out the infection should a case of this disease develop.

Testimonial Banquet to Prof. Elisha H. Gregory of St. Louis.—The St. Louis Medical Society of Missouri will tender a testimonial banquet, at Planter's Hotel, April 17, 1902, to Elisha Hall Gregory, M.D., LL.D., commemorating his fiftieth anniversary as a teacher of medicine. The committee having the matter in charge is composed of Drs. Lutz, Carson, Bryson, Hughes, Oulten, and Loeb.

Department of Physical Culture.—Senator Mason has recently introduced a bill providing for the establishment, under the Government, of a department of physical culture. Under this bill it is provided that the head of this department shall do everything he can to advance the cause of physical culture in improving the human race, as well as the improvement of the conditions under which people live. Among the purposes of the proposed department are the securing of shorter working hours, and the establishment of public playgrounds, gymnasia, public theatres, baths, laundries, etc.

Florida Medical Association.—The twenty-ninth annual meeting of the Florida Medical Association will be held at Tampa, Florida, April 9, 10, and 11, 1902.

New York Polyclinic.—Dr. M. D. Lederman has been elected Adjunct Professor of Laryngology and Rhinology at the New York Polyclinic Medical School and Hospital.

International Conference for the Prophylaxis of Syphilis.—The second meeting of the International Conference for the Prophylaxis of Syphilis and the Venereal Diseases will be held in Brussels, Belgium, September 15 to 20, of the current year.

Verdict Against a Hospital.—At a fourth trial of the action of Miss Helen D. Ward, sister-in-law of Henry E. Howland, the lawyer, to recover damages for personal injuries from St. Vincent's Hospital, a verdict for $18,000 was rendered before Justice Beach in the Supreme Court yesterday. Miss Ward had gone to the institution for an operation and, while recovering from the effects of the ether administered to her, a nurse applied a hot water bag scalding the patient. The suit was for $30,000 damages. At the first trial the complaint was dismissed. The jury disagreed at the second. The jury at the third trial gave her a verdict of $10,000. The judgment was set aside on appeal and the present trial ordered.

Defining the Status of Contract Dental Surgeons, recently added to the Army, the Secretary of War has decided that these dental surgeons have no official relation to the surgeon of a post, nor have their enlisted assistants—except that the latter may occasionally be attached to the hospital corps detachment for rations and quarters. When, for any reason, it becomes necessary to recommend the excuse from duty of an officer or enlisted man on account of dental disease, the contract dental surgeon will report the case to the surgeon of the post, who will take it up on his register of sick and wounded, but in other cases no report of dental operations will be made except by the contract dental surgeon.

Brevet Rank for Gallant Conduct.—A list of nominations of army officers to brevet rank for gallant conduct during the war with Spain and since, recently sent by President Roosevelt to the Senate and confirmed by that body, includes the names of a large number of surgeons of the regular army and volunteer forces.

The following were advanced one grade by brevet, "for distinguished conduct in the presence of the enemy in attending wounded under fire, Santiago, Cuba, July 1, 1898":

Major Rudolph G. Ebert, Surgeon, U. S. A.; Major Henry S. Kilbourne, Surgeon, U. S. A.; Major Samuel Q. Robinson, Surgeon, U. S. A.; Capt. W. B. Banister, Assistant Surgeon, U. S. A.; Capt. Henry C. Fisher, Assistant Surgeon, U. S. A.; Lieut. L. A. Fuller, Assistant Surgeon, U. S. A.; Lieut. T. J. Kirkpatrick, Assistant Surgeon, U. S. A.; Capt. James Stafford, Assistant Surgeon, Seventy-first New York Volunteers; Lieut. James R. Church, Assistant Surgeon, First U. S. Volunteer Cavalry; Major W. D. McCaw, Brigade Surgeon, U. S. Volunteers (Captain, Assistant Surgeon, U. S. A.).

Other brevet advancements were as follows:

Capt. Paul Shillock, Assistant Surgeon, U. S. A., "for distinguished gallantry in action near Taluan Samar, Philippine Islands."

Major Charles M Drake, Surgeon, U S Volunteers, "for distinguished gallantry in action at San Fernando, Luzon."

Major Henry F Hoyt, Surgeon U S Volunteers, "for distinguished gallantry in action near Mariliao, Luzon."

Major Paul F Straub, Surgeon, Thirty-sixth U S Volunteers (Captain Assistant Surgeon U S A), "for distinguished gallantry in action at Florida Blanca, Luzon."

Major George F Shiels, Surgeon, U. S. Volunteers, "for distinguished gallantry in action at the Tulichan River, Luzon, March 25, 1899, at the Grande River, Luzon, April 27, 1899, and at the Zapote River, June 13, 1899."

Capt George W Mathews, Assistant Surgeon, Thirty-sixth U S Volunteers (Lieut., Assistant Surgeon U S A), "for distinguished gallantry in action near Porac, Luzon."

Lieut Isaac W Brewer, Assistant Surgeon, Thirty-sixth U S Volunteers, "for distinguished gallantry in action near Florida Blanca, Luzon."

Intemperance and Disease in the Army.—In view of the rapid increase of certain diseases among troops in the Philippines, and at other tropical stations, an order has been issued to commanding officers enjoining upon them the strictest scrutiny over the habits and morals of their subordinates, and requesting them by personal example to influence the soldiers to preserve their health, both by abstaining from drink and the liability of contracting preventable disease. The order says, in part

"The only really efficient way in which to control the diseases due to immorality is to diminish the vice which is the cause of these diseases. Excessive indulgence in strong drink is absolutely certain to ruin any man, physically and morally; while disease due to licentiousness produces effects which are quite as destructive and even more loathsome. It is the duty of regimental, and particularly of company officers, to try, by precept and example, to point out to the men under their control, and particularly to the younger men, the inevitable misery and disaster which follow intemperance, moral intemperance and vicious living. The officers should, of course, always remember that the effect of what they say must largely depend upon the lives they themselves lead."

The Cure of Chronic Bright's Disease by Operation.—Dr. A. Rose writes: "Permit me to correct a printer's error which I noticed in my letter under the above heading published in the recent issue of your esteemed journal. It reads that Rose (E. Rose, not N. Rose) performed 'nephrectomy,' while I had meant 'nephropexy.' The reader will recognize the error, because this operation of Rose's is mentioned again in the same paragraph as nephropexy. I may, notwithstanding, be allowed to waive all responsibility for such a barbarous word in my writings as 'nephrectomy' for two reasons: first, because ectomy means castration; and, second, in Greek the preposition 'ec' cannot be used in the middle of a synthesis."

The Graduation Exercises of the Army Medical School, Washington, D. C., will be held in the hall of the National Museum on April 4, when twenty-three young army medical officers will have completed a five-months' course of instruction intended to fit them to enter upon a military career. The exercises include the delivery of an oration by Surgeon-General Sternberg, the founder of the Army Medical School, the presentation of diplomas by Secretary of War Root, and an address by Lieutenant General Miles commanding the Army. Immediately after graduation the student officers will leave for the Philippines where they have been ordered for duty. The course of instruction given at the Army Medical School is intended to amplify or supplement the professional training given by the ordinary medical schools, and pays special attention to the subjects in which the courses given in the latter are notably deficient. Particular importance is attached to the sanitary training of the army medical officer, eleven hours weekly being devoted to military hygiene and sanitary chemistry, and ten hours weekly to bacteriology and clinical microscopy. Military medicine and surgery, optometry, duties of the medical officer and hospital corps, drill and first aid are also taught, so that the young medical officer is sent out to his first station well equipped for the performance of his new duties.

Resolutions of the New York Obstetrical Society in the Death of Dr. Paul F. Mundé.—*Resolved*, That in the death of Dr. Paul F. Mundé, we have lost an old friend and comrade, who for over a quarter of a century has been foremost in our counsels and scientific work. Strong and aggressive in his personality, but always generous and warm-hearted, we shall remember him as one who rose by his own efforts to a place of great honor, but never lowered his standard of professional duty.

Resolved, That this resolution be inserted in our minutes and that a copy be sent to the family of our late Fellow.

J. E. JANVRIN, M.D., }
CLEMENT CLEVELAND, M.D. } *Committee*
HENRY C. COE, M.D., }

Cholera at Manila.—Asiatic cholera has appeared in Manila, sixteen cases with fifteen deaths having been thus far reported. It is believed that the disease was introduced from Hong Kong. Strict quarantine has been enforced.

To Study Cancer.—Provision is made for an investigation into the best method of treating cancer by an appropriation of $15,000 in the annual supply bill embodied in an amendment by the Senate Finance Committee. The money is to be spent at the Laboratory, in Buffalo.

New York Infant Asylum.—Dr. Charles Gilmore Kerley has been appointed Attending Physician to the New York Infant Asylum, West Sixty-first street and Amsterdam avenue.

The Pure Food Bills.—There are now two pure food bills before Congress. One, known as the Corliss bill, is discriminative in its provisions and is supported principally by the Retail Dealers' Association, while the other, known as the Hepburn bill, requires that every article offered for sale shall be branded or marked just what it is.

Addition to the Newport (R. I.) Hospital.—A new ward for this hospital is being built by Mrs. Cornelius Vanderbilt as a memorial to her deceased husband. This building, which is to be constructed of limestone, is to be one hundred and twenty-five feet long, forty feet wide at either end and fifty feet in the center. It is to be three stories high. The first floor will be for the treatment of outdoor patients, the second and third floors will be arranged in rooms, with a separate children's room.

Kaiser's Decree with Respect to the Use of Preservatives in Meat Products.—The Emperor of Germany has recently issued a decree which enforces stringent laws against the use of preservatives in meat products. This decree will hurt American exports in such products considerably. According to the

New York Herald, "the German Government's contention on boracic meat is not a protective tariff question, but is simply in the interests of health. Its exclusion rests on the results of experiments made by the Imperial Health Office. If the United States Agricultural Department can demonstrate to the Imperial Health Office that boracic meat is not deleterious, no political object will stand in the way of admitting it from America."

Philadelphia Polyclinic.—Dr. J. Alison Scott has been elected professor of Clinical Medicine and Therapeutics in succession to Dr. S. Solis-Cohen, resigned.

Automobile Accidents in Paris.—The Paris correspondent of the *New York Tribune* writes from the French capital on March 22, telling, among other news, of the many injuries and even fatalities caused by automobiles. The writer, after mentioning that at the date of his letter the casualty list was two killed and fourteen wounded during the preceding ten days, goes on to quote from the *Soleil* on the subject. A leading article in that journal declares that the disease known as speed insanity has broken out in Paris, and urges the Legislature either to stop automobile circulation in Paris altogether, or else to see to it that the city ordinances are strictly observed. It might be judicious to follow such a course in New York also. At present reckless automobile drivers are often a terror to the unwary pedestrian. In connection with this matter, it may be said that the Cocks bill limiting the speed of automobiles has been passed by the Assembly.

Concentration Camps in South Africa.—These camps are said to be now in a far better condition than they were a few weeks ago. The committee of women who went to South Africa at the instigation of the British Government for the purpose of making a careful investigation into the actual state of things prevailing in the camps, have reported that many former statements on the subject were greatly exaggerated; the death-rate among the children is still large, but the food is good and sufficient, the sanitary arrangements are as efficient as could be expected under the circumstances, and that, upon the whole, no grave cause of complaint can be brought against the authorities on the score of inhumanity or of neglect.

The Water Supply of London.—There are many schemes on foot to furnish London with a pure and sufficiently large water supply. An expert, writing on the question recently in an English magazine, gives a description of the various plans suggested, the most ambitious of which is that of the retiring engineer to the London County Council. Briefly, he proposes to bring, by the simple action of gravitation, an additional 200,000,000 gallons a day all the way from Wales to London. This will insure a total supply of 500,000,000 gallons a day, but if at some distant date even this enormous quantity should prove insufficient, the scheme provides for a second line of aqueduct to bring yet another 200,000,000 gallons.

Seizure of Meat Condemned as Unfit.—Inspectors of the Health Department seized, on March 22, at Washington Market, large quantities of veal alleged to be unfit for human consumption. The action was taken upon information given to Dr. Ernst Lederle by Charles A. Wieting, State Commissioner of Agriculture. It is said that 62,085 pounds of so-called "bob" veal were seized and destroyed in New York City during the week ended March 22.

Miss Addams on the Sweatshop Evil.—The New York *Herald*, March 23, contains an abbreviated account of a lecture on the subject given on Saturday morning, March 22. Miss Addams said in part that the Chicago charitable arrangements were much more primitive than those of New York. Speaking of the sweatshop system, the lecturer said that a woman working in the sweatshops in order to earn enough to support her children was not able even during the rush season to lay aside anything for use during the dull times. The principles upon which the sweating system is carried on are wrong in every respect, whether regarded from the standpoint of health or morals. It would seem to be in the interests of all concerned that the authorities should investigate the question, and abolish at least the most glaring defects of the system.

Charges Against Physicians.—The *New York Herald*, March 23, reports that charges are being made against Dr. Allen Fitch and Dr. Austin Flint, in a suit for large damages brought against them by a Mrs. Egan, who claims that by means of their connivance she was detained in an insane asylum, when, as a matter of fact, she was in full possession of her senses. The physicians in question, as might be expected, rebut these charges.

Plague in India.—The latest reports from India, with regard to the plague, reveal a fearful condition of affairs in some parts of that country. The death rate is appalling. One dispatch to the Exchange Telegraph Company from Lahore, Punjab Province, March 22, places the mortality at two thousand daily. It is said to be the worst epidemic on record, and the failure of the authorities to check its spread is largely due to the policy of non-interference where caste customs are concerned.

Gift in Aid of Medical Research in Liverpool.—Mr. William Johnston, a wealthy shipowner of Liverpool, has just donated the sum of $125,000 to the university of that city, $50,000 of which is to be set aside to found a chair of chemical biology; $30,000, at 5 per cent. interest, for the permanent endowment of three Research Fellowships of $500 a year each, and the remaining $45,000 to be spent in building a laboratory for the accommodation of the Tropical School, the professors of chemical biology, experimental medicine, comparative pathology, and the serum research department.

Distribution of Plague.—As regards the Mauritius, a telegram from the Governor, received on February 28, states that for the week ending February 27 there were seven cases of bubonic plague, three of which proved fatal. As regards Egypt, during the week ending February 23, eight cases and five deaths from plague have been reported from all Egypt. All these cases occurred among the native population.—*Lancet.*

Diagnosis of Smallpox in London.—The *London Hospital* says that, in order to facilitate the diagnosis of smallpox, the London County Council has issued a list of medical men in different parts of London who are willing to be consulted in doubtful cases of chicken-pox, the Council paying the necessary fee.

The Cure of Lupus.—According to the *Medical Press*, March 12, the Emperor of Austria has given $4,200 from his private purse for the foundation of an institute for the cure of lupus.

Compulsory Vaccination in France.—The news has been recently announced that at last France has adopted compulsory vaccination and re-vaccination.

Treatment of Inebriety in Victoria, Australia.—The *Australasian Medical Gazette*, 1902, states that a committee has been formed in Victoria, to investigate the different cures for inebriety. About half a dozen methods of treating alcoholics have been brought to the committee's notice, and many in-

[illegible] have submitted themselves as willing to be treated.

Memorial to the Late Sir William MacCormac.—It has been decided to erect a permanent memorial to the memory of the late Sir William MacCormac in form of a bust, to be placed in the central hall of St. Thomas' Hospital, the institution with which he was so long connected.

Complete Excision of the Stomach for Cancer.—The operation of excision of the whole stomach, which was performed by Mr. R. H. Parry at the Victoria Hospital, Glasgow, on February 14. The case was one of extensive malignant disease, and the patient has so far made favorable progress. It is believed to be the first time that the operation has been performed successfully in Scotland.—*Lancet.*

Dr. Thomas Dunn English Ill.—Dr. English, the venerable poet and author of the world-famed song, "Ben Bolt," is lying ill at his residence, Newark, N. J.

Obituary Notes.—Dr. W. W. JOHNSTON of Washington, D. C., died March 22 in Atlantic City, N. J., of pericarditis. He was one of the best known physicians in Washington. During the closing hours of President McKinley's life he was summoned to Buffalo to consult with the physicians in attendance there, but arrived too late to be of any service. He was about fifty-nine years of age. A widow, four daughters and two sons survive him.

Dr. ROBERT G. ELLEGOOD died at Laurel, Del., on March 22, at the age of seventy-four years. He was graduated from the Philadelphia Medical School in 1852.

Dr. OREN DAY POMEROY of this city, the well-known eye and ear specialist, died March 20 of apoplexy, at Whitestone, L. I. He was sixty-eight years old. He was the author of several standard works on his specialty; was surgeon to the Manhattan Eye and Ear Hospital, ophthalmic and aural surgeon to the New York Infant Asylum, and consulting surgeon to the Paterson (N. J.) Eye and Ear Infirmary. He gave up active practice several years ago on account of failing health.

Dr. GEORGE W. CUSHING of Brooklyn, N. Y., the well-known gynecologist, died on March 20, at his home, at the age of fifty-three. He was a lecturer, a member of the Kings County Medical Society, the New York State Medical Society, and Long Island Council of the Royal Arcanum. He is survived by a son and a daughter.

Dr. JOHN E. RICHARDSON, who has been ill for a year with cancer, died March 22 at his home, No. 127 South Oxford street, Brooklyn. Two daughters and two sons survive him. He was born fifty-one years ago at Albany, and was the son of "Deacon" William Richardson, former President of the Atlantic Avenue Railroad Company. He received his early education at the Brooklyn Polytechnic Institute, and began work as receiving teller in the Broadway Bank. Later he took up the study of medicine, graduated from the College of the Physicians and Surgeons in 1877, and spent several years at Vienna and Berlin. He later became an interne of the Brooklyn Hospital. For a number of years he was the chief surgeon of the Long Island Railroad, the Atlantic Avenue Railroad, and of the Brooklyn police. He was a member of the Oxford Riding and Driving, and Crescent Athletic Clubs of Brooklyn.

Dr. MAURICIO W. GILLMER died of pneumonia in Philadelphia on March 17, at the age of forty years. He was born in Brazil, where his father was American Minister, and was graduated from Jefferson Medical College in 1881.

Correspondence.

OUR LONDON LETTER.

(From our own Correspondent.)

[illegible]

London, March [illegible], 1902.

Many governments have treated the wishes of the medical profession with indifference, at times almost with contempt. The present cabinet seems inclined to be distinctly hostile, though one might have imagined that its political troubles were sufficient to make it unwilling to incur further [illegible]. It may be admitted that the apathy of the profession, and its reluctance to use its influence on political matters, have encouraged this attitude of successive ministries. It is certainly time for the profession to wake up. Look at the Midwives' Bill, which threatens to establish an inferior order of practitioners. The mass of the profession is dead against it—only a few selfish supporters of the illegal action of the Obstetrical Society are in its favor. Even the General Medical Council, at the last meeting, reaffirmed its resolution against it.

What matters it? The council has before been flouted by ministers, and now the Home Secretary pleaded for the bill that it gave less than many of its supporters asked for! And who are these supporters? Women—so-called philanthropic women—who want to push the employment of the sex, and the few accoucheurs who, to please them, betray their profession.

The Obstetrical Society ought to know that their diploma traffic has been more than once a cover for abortionists—a danger ever present among ignorant women.

This Government, which is again flouting the profession, is the inventor of the "conscientious objector" to vaccination, and has only recently refused to annul its action in this matter—and that in face of an epidemic of smallpox. The excuse is that the act will expire next year, and then may not be renewed. But we do not forget that it was only passed by dangling before opponents the prospect of legislation as to revaccination, which prospect is as distant as ever.

Though not exactly a medical measure, the profession has a special interest in the water supply, and the new bill of the government is condemned by all medical and sanitary experts. But we must leave the opposition to the rate payers, who are to be saddled by it with some £5,000,000 in excess of the value of the present investments as a sop to rich shareholders, and the control of the supply is to be handed over, not to representatives of the ratepayers, but to a cumbrous board of sixty-nine members irresponsible to those who have to find the millions!

Cardiac pain was discussed at the Medical Society on the 24th ult., when Dr. Markham Skerritt read the paper. Passing lightly by the protective influence of pain generally, and excluding neuralgia and acute diseases, he pointed out that disturbance of the balance between power and work may give rise to pain in various degrees of intensity, in normal as well as diseased hearts. Thus over-exertion, particularly by persons out of condition, will bring on severe pain when the heart is quite sound; but then rest will quickly relieve. He regarded vasomotor angina as due to excessive peripheral resistance, amounting to spasmodic contraction of the vessels, and, hence, painful embarrassment of the heart's action; sometimes contraction of the coronary vessels might add anæmia of the cardiac muscle. This angina is seen in early adult life, and in neurotic women at the climacteric, and in men from abuse of tobacco or alcohol. It may be induced by cold, by sudden exertion, with excitement, and by emotional disturbances. Blood conditions conduce to it, as uric acid, absorption of ptomaines from the bowel, and some drugs. Dr. Skerritt next considered pain when the heart was diseased. Valvular disease was not an important cause of angina. It is most frequently met with in aortic cases and, in Dr. Skerritt's experience, in regurgitation, though other observers have found it more common in stenosis. In the latter, compensation by hypertrophy may restore the balance between power and work, but in regurgitation the ventricle is so severely taxed that dilatation and hypertrophy ensue, and, later, degeneration of the wall—conditions likely to lead to distress and pain. When the coronary arteries were affected, degeneration of the walls would follow, and the enfeebled heart could not do its work without giving signs of distress. The distress would be much greater if arterial tension were increased—say, by renal disease or senile degeneration of vessels.

The various theories of angina pectoris were then mentioned. As to the treatment of cardiac pain, Dr. Skerritt said it was easier to lessen the work of the heart than to increase its power. Hence, the use of vasodilator drugs to diminish vascular tension.

Dr. Symes Thompson would have liked to hear more about the treatment of the pain. He thought functional disorder gave rise to the pain more frequently than organic lesions, instancing hysteria and hypochondria, to which I would add dyspepsia as still more common. Dr. Sansom would discard the word functional, as he thought it probable there was always some organic change. Nothnagel's vasomotor angina gave rise to discomfort, rather than pain. The right heart was first affected, but soon recovered, from over-exertion, which was less mischievous than usually supposed. In athletics hypertrophy of the left ventricle was not a harmful thing within due limits. He had seen relief from regulated exercises, but the cases in which cardiac was persistent were very few.

Dr. de Haviland Hall thought hepatic colic was sometimes mistaken for cardiac pain, and described a case which was benefited by blue pill and white mixture after nitrites failed, and which later proved to be due to gallstones.

Dr. Allchin said that usually in cardiac disease the pain radiated over a large area, especially along the left arm. Visceral disease gave rise to little pain until the serous coat was involved. He thought degeneration of the walls the most frequent cause of angina. He said the heart muscle differed from others, as it was not liable to cramp—which term should not be used concerning it.

Dr. A. Morison thought the term cramp useful.

In some fatal cases of angina fragmentation of muscle had been noticed which might possibly indicate rupture of fibers during an attack. He considered that the pain originated in the heart itself, and suggested some irritation of the nerve supply, which was very rich about the coronary arteries and aortic orifice.

Dr. Rolleston doubted if fragmentation was evidence of cramp; it was more likely to be produced by rigor mortis.

Dr. P. Weber favored the localized cramp theory of angina, and referred to the defective removal of the waste products of muscular action.

Dr. Pasteur said pain was rare when compared with distress. The worst cases were due to degeneration.

Dr. H. C. Pope said the pain was sometimes referred to the right side, as well as the left, and mentioned a case of sudden death when there had been no anginal attack, but atheroma of the coronary vessels was found. He thought tea was a common cause of pain in the cardiac region.

The R. B. Anderson fund has not received the support it deserved. The late Dr. Anderson sacrificed himself on behalf of his rights and his profession, and if medical men went into the case as they should, they would raise a couple of thousand more easily than they have done a couple of hundred. His case originated an association for the defense of civil rights, but that does not seem to have done much.

The annual meeting of the Medico-Chirurgical Society was held on the 1st inst. The retiring president, Dr. Pavy, delivered his address, commemorating the Fellows who died during the year.

The report of the council was adopted, after some discussion, as to letting a part of the premises. Mr. Alfred Willett was elected president for the ensuing year.

The smallpox cases for the last four days have been ninety, seventy, fifty-six, and sixty-nine. The number in hospital is approaching 1,500.

Influenza is spreading.

Dr. Seymour G. Toller of Cairo, where he was hospital physician and professor of clinical medicine, died on the 19th inst. He was only thirty-five years old, but he had achieved no little success. Four or five years ago he was elected on the staff of St. Thomas's Hospital, but was soon obliged to resign on account of ill health. Tuberculosis attacked him and he went to Egypt. There he worked actively, but, like many other brilliant men, eventually succumbed at so early an age that his friends ask each other what might he not have done had he had good health and longer life?

Among other recent deaths are R. T. Kent, M.A., Oxon. F.R.C.S., late Professor of Anatomy, Glasgow, aged forty-eight years.

Dr. Maxwell Simpson, M.D., LL.D., F.R.S., aged eighty-seven years, on February 26.

Dr. Ernest Elliott, late R.N., on February 27, aged eighty-four years.

Dr. S. A. K. Strahan, M.D., and also a Barrister-at-Law, died suddenly on the 21st ult., aged forty-eight years.

W. H. Cooke, M.D., J.P. of Aldridge, Staffordshire, on the 20th ult., aged sixty-seven years.

Dr. T. W. Pearse of Plymouth died there on the 20th ult., aged seventy-four years. His labors there in the cholera epidemic in 1849 are gratefully remembered. Another Plymouth senior was Dr. J. H. Eccles, Consulting Surgeon to the Eye Infirmary, who died on the 1st of March, aged eighty-seven years.

Fleet-Surgeon Henry Beaumont, R.N., on the 12th ult., aged fifty-seven years. He served in the navy for twenty-one years, retiring on pension in 1891.

Dr. J. Loudon, on the 26th ult., aged seventy-seven years; the life-long friend of Livingstone.

Dr. J. N. Cooper of Acorington, on 26th ult., from an overdose of a narcotic.

SUCCESSFUL MEASURES FOR THE PREVENTION OF THE SPREAD OF SMALLPOX, ADOPTED AT THE NEW YORK STATE REFORMATORY AT ELMIRA.

To the Editor of the Medical Record:

Sir: In view of the prevalence of smallpox, and the ease with which the virus seems to find its way through the community, it may be of interest to the medical profession to note briefly the facts in connection with three cases which recently developed in the New York State Reformatory at Elmira, with the view of, perhaps, suggesting to those in charge of large institutions what may be done to prevent the spread of the disease.

Upon June 8, 1901, we received, from the jail at Goshen, N. Y., two prisoners, who, as is our usual custom, were at once bathed, vaccinated, furnished with new clothing, and placed, for purposes of culture and military drill, in what is institutionally termed the "Awkward Squad." On June 17 a communication by telephone was received from the sheriff in charge of the Goshen jail, informing me that a case of smallpox had been detected in the jail, and calling our attention to the two prisoners recently received by us from his institution. Of course, no time was lost in examining the prisoners, with the result that the temperature of one of them, whom, for convenience, we will hereafter refer to as "A.," was ascertained to be a little above the normal; the other, whom we will designate as "B.," having a normal temperature.

There is, at this institution, no isolated building suitable for the care of patients suffering from contagious diseases, hence the question as to what should be done with our "suspects" at once presented itself. Our hospital occupies four floors at the extreme end of the south extension of the main building; the second floor being utilized in the care of those suffering from contagious diseases, and after consideration it was decided to remove the suspected cases to this isolation ward, which consists of two large rooms, capable of accommodating twenty patients. The hospital is separated from the prison proper by a brick wall, in which are doorways leading to each ward, and there is also an elevator shaft communicating with all the wards. I immediately caused to be bricked up both the doorway leading from the contagious ward into the prison proper and also the one opening from the contagious ward into the elevator shaft, in this way completely cutting off direct communication between the isolation ward and the prison proper and shaftway; entrance to the ward being gained by means of a doorway cut for the purpose, and which opened directly from the ward into the prison yard, or enclosure. Prior to the placing of the "suspects" in this ward, a number of dishes and tight barrels, suitable for the reception of refuse, etc., were placed therein—no article of furniture, or other utensil whatsoever, being permitted to be taken to or from the ward after it received the "suspects." The only person having access to the ward was the assistant physician, Dr. Denis Lucey, who, directly upon receipt of the information, had assumed the entire charge of them.

All windows opening into the inner court of the institutions were kept closed, and the use of the rooms beneath the extemporized smallpox ward was discontinued. All openings for the admission of steam and water pipes were carefully closed with cement, as were also certain catch-basins situated in the main institutional halls, but communicating with a sewer coming from the hospital. In connection with this it may be interesting to note that several times during the progress of the disease this sewer beneath the hospital became obstructed, causing an overflow into the adjacent yard, and necessitating the taking up and repairing of the sewer. When this was done, however, precautions were taken to pour a considerable quantity of the bichloride of mercury (in the proportion of one to one thousand) into the sewage and about the opening, and, fortunately, no spread of the disease resulted from the temporary opening up of the sewer while making the repairs.

The ward is divided into two rooms, the inner being occupied by the patients. The food was brought to the door of the outer room by an attendant, who unlocked the door, placed the food within the outer room, and gained entrance and locking the door behind him, after which an immune inmate attendant, unlocking the door leading from the inner room to the outer, came to the entry room and carried the food to the patients within the inner room, upon each occasion locking the door after passing through. Care was taken to frequently sprinkle the floor of the outer room with a strong solution of bichloride of mercury, and as a further precaution, the yard about the hospital was similarly treated during the entire period in which the smallpox cases occupied the ward.

Upon the evening of June 18 A. commenced to exhibit marked symptoms of the disease, which developed and progressed until July 4, at which time this patient began to convalesce, and B. was taken with the disease. Upon July 9 another inmate of the institution, C., complained of pains in his back, etc., and was at once removed to the smallpox ward, and placed for observation in the outer room; we were, however, reasonably sure that he was infected with the disease, and additional symptoms of the disease appearing on the following morning, he was also placed in the inner room.

On August 26 the three cases were so far recovered as to be in a fit condition to be removed from the ward, and, together with the two immune attendants, were instructed to divest themselves of their clothing, and go into the outer room, where they took a bath (bichloride of mercury in the proportion of one to two thousand), after which they shaved themselves, clipped short their hair, and were then marched a distance of about fifty feet to the bath-house, where they were given a shower bath by means of the Gegenstrom apparatus. Immediately upon the removal of the inmates from the infected ward measures were adopted for the sterilization of the same, and one hundred and fifty pounds of sulphur ignited, after which the formaldehyde gas generator was put in operation. I might mention as an evidence of the effectiveness of this method of sterilization that, upon the conclusion of same, twelve mice and a considerable number of bugs were found dead upon the floor of the ward.

The convalescents, and the immune attendants, were then supplied with new clothing, the former being, for a period of two weeks, placed in cells for further observation, while the latter were returned to the contagious ward, which they further proceeded to cleanse with a solution of bichloride of mercury, after which the ward was newly whitewashed and painted. All of the wooden furniture which the ward contained was then destroyed, and the fragments placed in barrels, which, in turn, were tied up in sheets saturated with a bichloride of mercury solution (one to one thousand), the whole being finally loaded upon an old wagon, and drawn to a considerable distance from the institution, and wagon and contents burned.

After the immune attendants had completed the whitewashing and repainting, they were again bathed in a solution of bichloride of mercury, new clothing issued to them, and, on October 1, were removed from the ward.

While it is customary to vaccinate every inmate upon his arrival, some of the inmates had been in the institution for a number of years, hence it was deemed advisable to immediately vaccinate those whose periods of detention had exceeded four years. As a final means of precaution, however, we vaccinated the entire population, with the exception of those who were able to show two good scars of quite recent origin. Upon investigation, it was found that an attempt had been made to vaccinate A. about one year prior to his reception here, although no scar appeared. B. was vaccinated on June 18, "prior vaccination" after his arrival here. As there was no reaction from this vaccination, he was revaccinated a week later, and the scar exhibited evidence of taking a day or two before he came down with the smallpox. An attempt had been made to vaccinate C. in February, 1901, but the scar left by this appears not to be a normal vaccination mark, and, in all probability, he was not successfully vaccinated.

A careful search failed to reveal the means whereby the disease was transmitted to the inmate of the institution who was last stricken (C.), and it could not be found that he had been in contact with either of the two initial cases since their reception in the institution, and, as his cell was situated at a distance of 150 feet from the hospital, it is still a mystery as to how he contracted the disease. Our inmate population, at the time of the outbreak of the disease, numbered, approximately, 1,400, and to care for these we employ about 130 officers.

I might further add that, immediately following the removal of two "suspects" to the isolation ward, the cells which they had occupied since their reception here were disinfected and subjected to a thorough sterilizing, the apparatus employed for this purpose consisting of a wagon, constructed of iron, in which a fire of coals is ignited, the whole being then wheeled into the infected cell and connections made between the wagon and a blowing apparatus placed in the corridor outside. The blower is then set in motion, fanning the fire, which after a period of something like two hours produces a temperature in the cell of from 500° to 600° F., and it is kept at this point for about twenty minutes, the heat meantime rushing up through, and thoroughly sterilizing, the ventilating flue leading from the cell to the roof above. The clothing of all inmates immediately upon their reception here is placed in the steam sterilizer, and for a considerable period subjected to a steam pressure of about twenty-five pounds per square inch, hence, although the garments are afterward placed in our storeroom, to be eventually given out to inmates upon their release, we were in this instance not much alarmed at the possibility of harm arising from infection being carried in the clothing.

In conclusion, I would state that it has been our good fortune to be able to check, even in such a densely populated community as ours, the spread of the disease, and where, in our judgment, it further appeared necessary that the patients should be cared for in the same building in which were confined the non-infected prisoners, for the reason that each of the infected cases was a prisoner having to serve a maximum sentence of five years, and the establishment of a pest-house outside the institution would of necessity have afforded, especially during the night time, possibilities of escape, which, if successfully taken advantage of, would have resulted in the loosing into the community, not only of criminals, but of sources of infection as well.

Frank W. Robertson, M.D.,
General Superintendent New York State Reformatory, Elmira, N. Y.

NON-BRITISH VIEW OF BOER WAR

To the Editor of the Medical Record.

Sir: Your "London Letter" in the issue of March 15 throws a peculiar light upon some features of the deplorable conflict in South Africa. According to your correspondent, the British Government inspector of the concentration camps suggests that the continental critics "should see the camps themselves." Since when are they permitted to do so? But if allowed to make an inspection, they would see that "the Boer children in the camps have been all along faring better than the thousands of children of the poorer classes in England." And why, in the name of English humanity, is this war continued? Why not care better for the poor wretched children at home—and in Ireland? Such a condition goes far to explain the inability of a quarter of a million British soldiers, many from those poorer classes, to terminate the war.

Indeed, the examples given by your correspondent prove the "ignorance, credulity, and the extremely dirty habits of the Boer parents." I do not think they have grown that way under British protection in the camps; they certainly must have been ignorant, credulous, and dirty when living in freedom on their farms. And if these three factors are named as contributing to the extremely high mortality in the camps at present, they may be named with equal right as having contributed in the past to the production of a people whose endurance, heroic patriotism, and adherence to the rules of civilized warfare command the admiration of the greater part of civilization.

I do not wish to debate with your correspondent on this subject, I am simply opposing my non-British view to his view.

J. F. Baerecke, M.D.

CAN CHLOROFORM BE ADMINISTERED TO A SLEEPING PERSON WITHOUT AWAKENING HIM?

To the Editor of the Medical Record.

Sir: Perhaps as a result of the relative lack of study and non-use of chloroform in the Northern cities in America, we note what we consider to be incorrect evidence in the Rice case.

The report is that a Philadelphia doctor testified that he had never been able to administer chloroform to a sleeping patient without causing him to wake.

Unfortunately, the scientific value of expert testimony in the United States depends upon which side the expert testifies.

Without consulting works on medical jurisprudence, I am quite sure that the testimony of the doctor referred to is contrary to the experience of those who use chloroform, as the Southern profession does.

And there are numerous well-authenticated cases in which robbers have successfully chloroformed persons while they slept. And the *modus operandi* of the robber chloroformist gives a lesson to numerous doctors.

He does not use an appliance to be closed at one end by the subject's face and virtually closed at the other by cotton or by the hand of the anæsthetizer.

There has been much written as to whether chloroform kills by inhibition of the respiratory, or of the circulatory, centers. But after a long experience, it is entirely clear to the writer that most deaths from chloroform are indirectly due to the brain of the administrator. Formerly it was taught that chloroform was contraindicated in certain valvular defects of the heart, but if this were true, there would have been many more deaths recorded. Particular care is to be used in chloroforming muscular young men. With skill, with a pure article, given in the early morning hours, and preferably in the summer, chloroform is about as safe as is any other potent article in the pharmacopeia. THOS. R. EVANS, M.D.

BECKLEY, W. VA.

Progress of Medical Science.

The Boston Medical and Surgical Journal, March 20, 1902.

Case of Combined Extra- and Intra-Uterine Pregnancy.—H. P. Perkins reports a case in which the symptoms were of a perplexing nature, but led to a diagnosis of hematocele. Upon opening the abdomen from twenty to thirty ounces of fluid and clotted blood escaped. A mass of adherent tissue was broken through, and the bleeding point found to be in the right Fallopian tube, which was enlarged and ruptured close to the uterus. The ovary was found considerably enlarged and cystic, more than three-quarters of its structure being involved. Great care was taken not to disturb the uterus, in the hope of saving the normal pregnancy, but five days after the operation flowing began, and the remains of an eight weeks' fœtus had to be removed. The patient made a good recovery, and since the operation has had but two short hysterical attacks, whereas she was previously subject to hysteria, convulsions of minor grade, and occasional attacks of hystero-epilepsy. An interesting feature of the case is that the patient had had two mild attacks of appendicitis, and that during the operation the tip of the appendix was found to be adherent to the ovary, the appendicular-ovarian ligament being obliterated. The appendix contained no concretion or fecal matter, but was congested and swollen. It is probable that the diseased ovary had some influence in producing the inflammatory attacks of the appendix.

Osteo-Arthritis of the Spine; Spondylitis Deformans.—Joel E. Goldthwaite says that this disease is probably in part a trophic process, and consequently all medicines or methods of treatment which debilitate should be carefully avoided. This includes so-called rheumatic remedies, which are depressing if used for any length of time, and various baths or courses of treatment, which tend to debilitate. The general treatment should be nourishing and stimulating, care being taken to see that the eliminative functions are ample. Extra diet, stimulating bathing, massage of the unaffected parts, electricity in a mild current, are all of value, and also dry heat, if not used to the point of debilitating. Iron, arsenic, and strychnia are the drugs of greatest value, with phosphate of soda, the bicarbonate of potash, or such simple remedies as tend to increase the eliminative functions. Cod liver oil and alcohol, in medicinal doses, are also useful. The mechanical treatment consists chiefly of some form of support which will limit the motions at the seat of the disease. The disease is apparently aggravated by injury or irritation, and this must be prevented as far as possible. If the symptoms are very acute, complete fixation of the spine is indicated, and this is best accomplished by some form of support which entirely encircles the body. The author further describes apparatus and reports cases which are accompanied by very clear illustrations.

Journal of the American Medical Association, March 22, 1902.

The X-Ray in Determining the Limits of the Frontal Sinus.—J. H. Philip comments on the fact that the frontal sinus is sometimes lacking, thereby possibly leading to a wounding of the dura mater in operative work. He suggests the use of the x-ray to determine previous to operative intervention the existence and outlines of the sinus. He records the clinical history of a case in which this procedure was followed, and he found that the limits of the cavity were very clearly defined.

The Use of Tropa-Cocaine in Spinal Surgery.—W. P. Illing advises the use of this remedy, as it can be easily sterilized and is far less liable to cause untoward effects than is cocaine. Recovery from its effect is much more rapid. Upon the nerve centers it acts by first stimulating, then paralyzing from the brain down in decreasing degrees, but it prevents complete paralysis of the spinal cord or respiratory centers. Illing thinks its action is a little slower than cocaine hydrochlorate, and finds in using cocaine hydrochlorate that the anæsthesia usually appears in from four to ten minutes, while with tropa-cocaine it seldom appears earlier than ten minutes. After an injection of tropa-cocaine there is usually no complaint of thirst, heat, vomiting, pallor, nausea, or perspiration; no marked increase or decrease in the pulse; no facial expression of anxiety; no marked increase or decrease in respiration; no dyspnœa; but he has noticed relaxation of the sphincters, with involuntary evacuation of fæces, in two of his cases, which occurred while the patients were on the table; in one the bowels continued to move after being returned to bed. It is his belief that to obtain perfect anæsthesia we can safely count on one-sixth of a grain of tropa-cocaine producing anæsthesia for fifteen minutes, and sometimes even longer.

Prolonged Intubation.—E. Rosenthal would divide the causes of prolonged intubation into: (1) The type of disease; (2) The result of the disease or its sequel; and (3) The result of the operation, the wearing of the tube. Those familiar with the treatment of croup by intubation have noted a primary as well as a secondary type. The first, in which the disease begins in the larynx; the second, in which it is a continuation of a previous nasal or faucial condition. The latter may be taken as the type giving rise to prolonged intubation. By far the greatest or most frequent cause for prolonged intubation is referable to the sequelæ of the disease. The most common lesion is paralysis of the cords. Injuries are often caused by the presence of the tube. Its irritation sets up an inflammation, which, in its turn, results in edema or suppuration. Some authors claim that such results are chiefly due to traumatism—laceration produced by efforts in intubation or even extubation. Lacerations may be produced in the former by using too much force in an irregular attempt; in the latter, by missing the opening of the tube by the lips of the extracting instrument, and by dilating the blades during withdrawal. The most common condition met with in connection with prolonged intubation is edema, but this may also result from other causes. Rosenthal believes that hydrogen peroxide causes much irritation. Its use is permissible, but it should be employed in very weak solution.

A New Method of Dealing with Bowel Perforations Communicating with Pelvic Abscesses.—T. W. Huntington says that such lesions as are noted in the title of his article present a two-fold aspect: (1) As regards the immediate risk to life from general septic peritonitis and (2) As to the likelihood of establishing a permanent fecal fistula, with its external outlet through Douglas's pouch or through the abdominal wound. In a case of the nature under discussion, the bowel perforation was temporarily closed by a purse-string suture, the ends of the latter being left uncut and a sponge attached for identification. This was dropped into the pelvic cavity and the incision which had been made in the median line was closed. An anterior colostomy incision was then made over the sigmoid. Through this the buried sponge was recovered and the bowel perforation was drawn up into view. The bowel was then carefully sutured to the parietal peritoneum, thereby completing a formal colostomy. The median incision was sealed and a loose dressing applied to the lateral opening. Median line incision healed without interruption. All fecal matter passed by artificial opening subsequent to operation. Several days later an elliptical incision was made encircling the artificial anus, the peritoneum being opened throughout. Through this the colon was drawn out and exposed for a distance of three inches above and below the perforation. About four inches of the colon was resected. An end-to-end anastomosis was accomplished by the Connell suture method. The abdominal wound was then closed by through-and-through sutures.

New York Medical Journal, March 22, 1902.

Tripartition in the Study of the Female Pelvis.—By this term A. E. Gallant refers to a system of classification in the study of the female pelvis. He arranges its component parts under the three general headings of anatomical, functional and pathological. From this starting point he elaborates a series of charts, each main heading having throughout the entire system three subdivisions. He believes that this system has the following advantages: (1) It is conducive to consecutiveness, conciseness and clearness; (2) It aids the student to clearly comprehend, note and fix points, and (3) Is simple in its application to the individual patient.

Malnutrition as Shown in Congenital Syphilis. [illegible]

A Report on the Use of Antiphthisic Serum T. R. [illegible] ... These cases illustrate the [illegible] type of the disease in which all changes are slow and which are for the most part stationary. In the third class the period of failure dated from the beginning of treatment and ceased with its withdrawal. In the fourth class the patients improved during the treatment, but the writer does not attribute this to the treatment alone, as in the same number of equally favorable cases the results will be fully as good without any specific medication. The patients treated were all, with few exceptions, very favorable ones indeed, and excluding those in whom there is every reason to believe the serum positively injurious, the same results are attained as during a limited period of non-specific treatment; in a certain proportion of cases there is improvement, in others the condition remains stationary, and in still others, there is retrogression. The writer believes that the results of this treatment are nearly comparable to those obtained without it.

The Lancet, March 15, 1902.

Gangrene of the Skin During an Attack of Enteric Fever.—The history of a case is reported by A. S. Barrow. On the twenty-sixth day of the illness there was severe hemorrhage from the bowel, which was repeated twelve hours later, and the patient then passed into a typhoid state, from which it was difficult to arouse her. Two days after the hemorrhage a small bulla appeared over the left outer malleolus and a large bulla over the right buttock; in twenty-four hours the bulla shrivelled up, leaving a black patch beneath devoid of sensation. The site of the bulla over the malleolus formed a slough, which was removed, leaving a punctiform ulcer one inch long by half an inch wide, exposing the subcutaneous tissue. The site of the bulla over the buttock formed a slough more gradually, but, in ten days from the appearance of the bulla, a large slough was removed, which left a deep excavated ulcer with sharply-punched-out edges one and a quarter inches deep, three inches long, and two inches wide. The ulcer over the malleolus speedily healed, although that over the buttock took longer, but with the patient keeping the prone position, a good result was obtained. The patient never had a "bedsore," and was very carefully looked after by a trained nurse.

Rupture of the Coverings of an Umbilical Hernia with External Protrusion of the Intestine.—The patient of F. T. Travers was a woman, aged sixty years, who had a small umbilical hernia, and had suffered for some years from winter cough. During a coughing spell something "gave way." Examination one-half hour later revealed a mass of intestine protruding through an aperture in the side of the hernia. It was covered with folds of warm cyanide gauze and supported by bandaging until removal to hospital was accomplished. On arrival ether was at once administered, and after the cleansing of the abdominal wall the gauze wrapping was removed and about six feet of small intestine were found to be protruding from a rent one and a half inches across the side of an umbilical hernia. The gut was irrigated with warm chinosol solution (1 in 2500) and was wrapped in warm sterilized towels. The wound in the skin was enlarged till the bowel could be reduced. A portion of omentum which was adherent to the interior of the sac was ligatured and cut away, and the walls of the sac were freed and sutured. The sides of the opening in the fascia were laced together by a continuous suture, and after cutting out the portion of skin around the rent the wound was closed. After the operation, which occupied half an hour, the patient's condition appeared to be better; she, however, soon began to run down again, and died from cardiac failure thirty-eight hours later.

Anatomy, Physiology, and Pathology of the Imperfectly Descended Testis.—In the third Hunterian lecture, W. Y. Eccles continues the discussion on pathology, speaking first of cysts. Of these there are four varieties: (1) Cysts formed upon the epididymis; (2) Cysts found in the testis proper; (3) Cysts due to fœtal remains; and (4) Dermoid cysts, teratomata. In addition, malignant new growths may occur in the imperfectly descended testis, notably sarcoma and carcinoma. So also there may be a complicating hernia or a hydrocele. Concerning the former, Eccles says that a hernia which accompanies the testis into the tissues of the perineum may be designated a superficial perineal hernia, it being termed superficial to distinguish it from that rare form of perineal hernia which leaves the pelvis through the gap in its floor. The course of the descent of a superficial perineal hernia is from the abdomen, along the canal, through the superficial ring, past the scrotum near its entrance, and then backwards toward the margin of the anus. This form of hernia is necessarily rare, for perineal ectopia of the testis is uncommon, and even when present, an accompanying hernia is seldom seen. It appears as an elastic swelling on one side of the perineum with an expansile impulse on cough, frequently resonant on percussion, and usually reducible on pressure. After the return of the contents of the sac the testis, sometimes well developed, can be felt lying by the side of the anus and often tethered by a band, probably of the gubernaculum, to the region of the external sphincter or tuberosity of the ischium.

Some Remarks upon "Internal Derangement" of the Knee Joint.—H. W. Allingham analyzes fifty-nine cases, all of which presented the usual features, with locking of the joint, or else weakness with recurrence of pain and swelling, which is often the only evidence of damaged semilunars. The following conditions were found: (1) Semilunar cartilage, internal or external, split, loosened or displaced, torn from either or both extremities or from coronary ligaments; (2) Loose bodies, quite free or attached by a pedicle; (3) A torn or hypertrophied alar ligament or hypertrophied fringe of synovial membrane; (4) Rheumatoid arthritis—roughened cartilage, thickened synovial membrane, and osteophytic outgrowth, and (5) No obvious derangement.

In the cases of damage to a semilunar cartilage there are generally these features: (1) Distinct history of injury originating the trouble; (2) A well-defined site of pain on the inner or outer side of the knee, according to the cartilage damaged; (3) No foreign body palpable; and (4) No creaking in the joint. These same features also characterize generally cases in which the lesion affects an alar ligament, or consists in localized hypertrophy of synovial membrane. In the cases in which a loose body is present, the symptoms, again, may be exactly similar to those caused by semilunar damage. Sometimes, however, the body will be able to be moved into widely-separated portions of the joint and felt in its different situations. Similarly, a very loose semilunar cartilage may sometimes be diagnosticated with certainty through its being protruded at the side of the joint. Such a cartilage, however, may be most confusingly imitated by an excrescence due to rheumatoid arthritis.

Certain Diseases of the Bloodvessels.—In the second Lettsomian lecture, A. Pearce Gould considers obliterative endarteritis, and gives at length the clinical histories of several cases. He alludes to the various theories of causation, but says that we really know so little of the ultimate causes and processes of disease that it is difficult to accept or to reject any of them. Of all known causes syphilis is perhaps the most certain; influenza, alcoholism, erythromelalgia, cold, contusions, and previous thrombosis or phlebitis may be regarded as more or less important factors in originating the disease. Diabetes sometimes causes gangrene by exciting this disease. Concerning treatment he says that, in the earlier and less advanced stages of the malady, prolonged rest of the affected part is certainly called for. Local warmth should be carefully supplied. Anodynes often in large quantities may be necessary for the relief of pain. Massage carefully carried out has also an important influence in furthering the opening out of collateral vessels, in promoting absorption through the lymphatics, and in freeing the muscles and other tissues of their waste products. In the acute stage the parts are too tender to admit of it; in all early cases it must be most cautiously employed; where the disease seems to be arrested and we have to deal with its effects only, it may be used a little more vigorously. Small, mummified areas may be left to separate naturally, especially in the hand. For more extensive gangrene, which is always of the "mixed" form, amputation is necessary; the relief to pain that the operation affords always reconciles the patient to the mutilation. The operation should be done high above the gangrenous spot and at a place and by a method that throws least strain upon the vessels of the part. Thus amputation through the lower part of the thigh is to be preferred to disarticulation at the knee, and musculo-cutaneous flaps are to be chosen in preference to skin flaps.

British Medical Journal, March 15, 1902.

Survival of a Premature Child Weighing Two Pounds; Sequel.—R. Jardine notes the birth of a child (six and one-half months) which was reared in an incubator. When she was dismissed from the hospital at four months of age she had gained from one and three-quarter pounds to slightly over three pounds in weight. At ten months she weighed six pounds and twelve ounces, but about two weeks later she died of broncho-pneumonia. She had been perfectly well till then and, with reasonable care, ought to have survived.

Posture and Heart Murmurs.—W. Gordon believes that recumbency tends to increase all "hæmic" murmurs except the venous hum, which it tends to obliterate, to increase the murmurs of initial regurgitation, tricuspid regurgitation, and aortic stenosis, and to leave little, if at all, affected, the murmur of aortic regurgitation. The effects of gravity and of change in chest depth seem to account for the influence of recumbency. Therefore, in describing and discussing murmurs which posture modifies, the patient's position at the time of observation should be stated.

A Plea for a More Continuous Treatment of Gastric Ulcer.—F. Gill approves of giving the stomach complete rest for a period of several weeks while an ulcer is healing. He has given his patients six to eight ounce injections, consisting of white of eggs, milk, and beef-tea, with liq.

[illegible] In one case where it was [illegible] the [illegible] was increased and the [illegible] The [illegible] as possible. The results of this treatment have [illegible]

On a Convenient Terminology for the Various Stages of the Malaria Parasite.—[illegible] Lenermann states that the malarial germ which is brought by the stab of the mosquito into the human blood [illegible] is a reproductive germ or spore. The [illegible] enters the blood by the agency of the mosquito's stab and immediately penetrates each one a red corpuscle. The amœbula [illegible] within the red corpuscle, enlarges and finally breaks up into [illegible] spores, which are liberated with destruction of the red corpuscle. The [illegible] penetrate fresh red blood corpuscles, and after a certain growth as amœbulæ break up into a new crop of [illegible]spores, by which the infection of the red corpuscles is extended. This process appears to go on for several generations and for a varying duration of time. The gametes or [illegible]spheres remain unchanged in the human blood. They are male and female. The zygote or sexually-produced embryo remains unchanged, but it [illegible] in size and becomes [illegible]. The spore-cysts lying outside the stomach wall of the mosquito, bathed in the insect's blood, receive abundant nourishment. The single-celled vermicule enclosed undergoes rapid changes, it increases greatly in volume and breaks up by internal cell division into a number of spore-mother cells. In the process of this division and the later stages of the final development of the "spores" (exotospores) the "spore-forming cyst" increases in size to twenty times its initial diameter. The spore-holding cysts burst and liberate the exotospores into the blood of the mosquito. Thence they readily pass into the ducts of the salivary gland, and so are conveyed by the mosquito's stabbing beak into human beings. The mosquito ejects the secretion of its salivary gland into the punctured wound which it makes in the human skin.

Deutsche medicinische Wochenschrift, February 27, 1902.

Etiology and Treatment of Pruritus Vulvæ.—L. Seeligmann discusses the essential or idiopathic form of this disease, which has been regarded in many quarters as generally neurotic in character. This disease is essentially different, both clinically and pathologically, from kraurosis vulvæ. The latter condition shows pathological changes in the connective tissue and nerve endings of the vulva, while these are absent in pure pruritus. The vulva in pruritus is œdematous, inflammatory and moist in appearance, while in kraurosis it is shrunken, dry, and has a grayish white color. Seeligmann has observed a considerable number of cases of pruritus in which no cause could be discovered. In such cases he obtained from the vulva in pure culture a diplococcus, which is very similar to the gonococcus in appearance, but which does not decolorize by Gram's stain, and which is readily cultivated in bouillon and upon gelatine, agar and potatoe. Inoculation experiments were not attempted. He regards this organism as the causative factor in the production of idiopathic pruritus vulvæ. In the treatment of this disease the author has for many years used guaiacol-[illegible] (10 per cent.) as a local application with marked success. Experimentation shows that this substance kills in a very short time the diplococcus isolated by Seeligmann. Occasionally it is necessary to increase the strength of the ointment to fifteen or twenty per cent. The vulva should be thoroughly cleansed before the application of the ointment, which is to be used once daily, preferably at night. Two or three applications generally suffice to bring about a cure.

Nephralgia, Nephritic Hematuria and Nephritis.—James Israel answers Senator's criticism (See MEDICAL RECORD, March 22, 1902) of his views concerning these diseases. Senator's contention that upon operation only one of the fourteen cases showed increased tension of the kidney and hence the results obtained by the incision of the organ in the remaining twelve could not be reasonably ascribed to the lessening of a tension which did not exist, is inappropriate, as Israel has always maintained that the congestion and consequent increased tension were periodical and not permanent in character, and were only present during the attacks of nephritic colic. No other assumption than this can be reasonably held, for if the increased tension is the cause of the colic as Israel believes, permanent increased tension would necessarily give rise to permanent pain, which is never present in these cases. Cases which are operated on during the colic disclose an increased tension of the kidney. Senator states that nephritic colic and hematuria are seldom seen in Bright's disease. Israel denies this, and claims that such an association is quite frequent.

Senator further says that there is no such condition as a unilateral Bright's. This is certainly true, since the name "Bright's Disease" has been reserved for those cases in which both kidneys are affected. There is no doubt, however, but that there occur unilateral kidney lesions which are identical with those found in Bright's disease. Various authors, including Israel, have reported numerous cases which prove this.

Berliner klinische Wochenschrift, March 3, 1902.

Functional Kidney Diagnosis.—Examinations made by F. Straus included: (1) An estimation of the molecular concentration of the urine by means of its freezing point. (2) A quantitative analysis of chlorides. (3) A quantitative analysis of the nitrogen, and (4) A quantitative analysis of sugar following phloridzin injection. The fact should be emphasized that the molecular concentration of the urine in any given case depends very largely upon the quantity of liquids ingested. Hence, in order that comparative results of value in freezing point tests be obtained it is necessary that a statement should be made in regard to the quantity of liquids ingested by the patient during a certain time previous to the examination. In examining his cases Straus estimated the functional activity of each kidney during the same period of time, also the functional activity of each kidney during the same length of time but at different periods. In this manner it was possible to compare the functional activity of the kidneys with each other and, furthermore, to make a comparative estimate of the activity of each kidney at different periods. In this way it was shown that under normal conditions the functional activity in toto of each kidney is the same during a given period, but that such activity constantly varies in each kidney both as compared with itself and with its neighbor. The same functional variation holds true under pathological conditions, but that kidney which is diseased shows the greatest variations.

Embolism of the Superior Mesenteric Artery.—R. Sievers reports the case of a woman, fifty-six years of age, who for about nine months had complained of marked asthmatic symptoms. During this time a left-sided pleural effusion, œdema of the lower extremities, and a small amount of ascites had been present. All of these symptoms had, however, been favorably influenced by the administration of strophanthus and diuretin. The heart was irregular in action, but the sounds were clear. The urine contained a large amount of albumen. She was suddenly seized with severe abdominal pain, accompanied by nausea and vomiting. Great prostration developed, and the pulse became so weak that it could only be counted with difficulty. The entire abdomen became swollen and slightly tender upon pressure. Constipation with marked tenesmus was present, but no fever. No intestinal hemorrhage occurred. The severity of the symptoms rapidly increased, and death took place within twenty-nine hours from the beginning of the attack. Upon autopsy an aneurism of the decending aorta was found opposite the fourth and fifth dorsal vertebra. The aneurism contained a thrombic mass, upon removal of which it was seen that its internal wall was markedly sclerotic and lined with chalk plates. A non-adherent thrombus 6 cm. long was found lodged in the superior mesenteric artery near its origin from the abdominal aorta. This case adds another instance to those which have previously been reported in which embolism of the superior mesenteric artery is not accompanied by intestinal hemorrhage, and shows that such is in no way pathognomonic of this condition.

Acute Syphilitic Nephritis.—Erich Hoffman reports the exhaustive study of a case of acute syphilitic nephritis, the existence of which has been denied by many authors. On presentation the patient showed a mixed syphilitic eruption, which was partly macular and partly papular in character. The initial lesion had been received about two months previous and was still apparent. There was a generalized enlargement of the superficial lymphatic glands. Mucous patches were present in the mouth. The patient was very intelligent, and, upon close questioning, gave no history, either hereditary or personal, of any previous kidney disease. He stated that about two weeks previous he had noticed a sudden change in the character and quantity of his urine in that it had been markedly reduced in quantity and had appeared of a dark-red color, becoming solid on boiling. Its specific gravity was 1057, and a large number of hyaline casts were found, and also a small number of leucocytes and red blood cells and a few renal epithelial cells. A quantitative estimation of the albumen showed that it was present in 7 per cent. by weight in one specimen and in 8 per cent. in another. Under anti-syphilitic treatment the cutaneous syphilitic manifestations and the urine gradually improved. Soon thereafter the patient was lost sight of, but returned in two months with a recrudescence of symptoms. Iodide of potash and mercury were given. The albumen rapidly disappeared from the urine and the eruption gradually vanished. Hoffman thinks that this case is, without doubt, one of acute syphilitic nephritis. Many authors have regarded syphilitic nephritis as always of the hemorrhagic type. This case shows that this view is not always correct. Hoffman thinks that the microscopical examination proves that the nephritis is produced by the action of the syphilitic poisons upon the bloodvessels of the kidney, especially of those of the glomeruli.

Munchener medicinische Wochenschrift, February 25 and March 4, 1902.

Treatment of Tuberculous Joint Affections of the Lower Extremities.—Wagner points out the fact that in addition to fixation, removal of pressure and extension, certain other measures are necessary in order to obtain the best results in the treatment of tuberculous joint affections of the lower extremities. In all cases a certain amount of exercise in the open air is necessary, and sea or salt-water baths are of great utility. Hitherto these measures have been principally used in the earliest stages of this disease or as an after-cure. The reason why these means have not been more generally employed during the acute stage is that they have been thought incompatible with proper fixation and extension, which are imperative during this period. The combined use, however, of the so-called "lime" bandage and Hessing's apparatus satisfactorily secure the latter objects and render possible at the same time the employment of the above hygienic measures. During the bath the Hessing apparatus may be removed and the "lime" bandage protected from the water by a rubber covering or by moistening with a few drops of formalin, which answers the same purpose. Experience has shown that cases treated systematically in this manner progress more favorably than those treated solely by fixation and extension.

A Case of Puerperal Fever which Gave a Positive Widal Reaction.—Felix Sommel reports a case of puerperal fever which gave a positive Widal reaction in a one to eighty dilution. For this reason the diagnosis of typhoid fever was made. Death took place and the true nature of the condition was discovered at the autopsy. The fever developed on the second day following labor and a primary diagnosis of puerperal fever was made. Appropriate treatment was instituted without success. The fever continued unabated for a week, when, upon examination, the spleen was found enlarged. A Widal test conducted at this time under all precautions was positive (one to eighty). Only one test was made. The urine contained a small amount of albumen. On the following day death took place. At the autopsy no typhoid lesions were found, but the uterus was found in a state of septic inflammation. No bacteriological work was done in connection with the case, and the exact microbic basis of the disease was not ascertained. The author reviews the literature of the past few years which relates to the interagglutination between colon and typhoid bacilli and comes to the conclusion that in this case the uterine infection was due to the former microorganism either alone or in combination with some other microbe, and that the presence of the positive Widal is to be accounted for on this supposition.

Avoidable Appendicitis Complications.—A. J. Ochsner considers the following as avoidable appendicitis complications: Circumscribed and general peritonitis, infection of the tubes and ovaries, infections of the gall bladder, abscess of the liver, empyema, endocarditis, meningitis, various joint infections and metastatic abscesses in different parts of the body. Ochsner believes that the inflammatory process may be localized by the following treatment: All nutrition by the mouth should be withheld and the stomach washed out. Small quantities of hot water should be given by the mouth at frequent intervals, with nutrient enemata of four ounces each four times a day. Cathartics and large enemata should be avoided. Absolute rest in the horizontal position should, of course, be enforced. In this manner the small and large intestine, together with all the tissues in the region of the appendix, are put completely at rest, and the localization of the infection to the appendix is strongly favored. This is shown by the marked improvement in the local and systemic symptoms. After a few days the appendix is removed without the infection of other tissues. Even when the appendix is gangrenous and perforation has taken place the infection may be localized by carrying out this plan of treatment. The author reports 620 cases of appendicitis which have come under his observation during the last three and one-half years. Twenty-one of these showed a complicating general peritonitis. Four of the latter were moribund when first seen and died without operation. The remaining seventeen were treated in the above manner and operated on after the subsidence of acute symptoms. Of these, eight (55 per cent.) died; 192 showed perforated or gangrenous appendices with beginning circumscribed or general peritonitis. Treated similarly, nine (5 per cent.) died; 407 were first seen during the interval or within the first thirty-six hours of the attack. They were operated on immediately. One (¼ per cent.) died.

Jolles' Clinical Ferrometer.—E. Boetzelen reports the use of the improved ferrometer recently devised by Jolles. The estimation of the amount of iron in the blood is made by comparing the color of the solution to be tested with that of a graduated colored glass wedge similar to that used in the Fleischl-Miescher hemometer. Boetzelen first tested this ferrometer by the means of solutions containing a known amount of iron, and found that the readings obtained were correct. He then examined a number of normal individuals, and found that in men the normal reading was 85 to 98, while in women it was 80 to 92. Lower readings may be considered pathological. In health the ferrometer and hemometer readings are practically identical. In disease, however, they may show wide variation.

Use of Alcohol in Tuberculosis.—As the result of experimental and statistical research, St. Mircoli believes that alcohol is of undoubted use in the treatment of tuberculosis. The blood serum of many healthy individuals possesses antitoxic properties when added to Maragliano's tuberculin and inoculated into guinea-pigs. Under these conditions such serum is often able to entirely protect the animals against the development of tuberculosis. The serum of alcoholics in good general condition shows much more antitoxic power than does the serum of non-alcoholics. In those alcoholics, however, in whom alcohol has produced pathological changes, particularly of the nervous system, the blood serum possesses very little antitoxic power. Such pathological effusions as ascitic fluid show marked antitoxic power. From a statistical review, the author shows that among moderate users of alcohol tuberculosis is less frequent than it is among total abstainers. From these observations, and as the result of further experimentations, the following conclusions may be drawn: (1) Alcohol in proper amount aids the body in its endeavors to produce an immunity to tuberculosis; (2) Its internal and local use in this disease is therefore recommended; (3) The result of statistical research adds strength to this recommendation. It is to be remembered, however, that the excessive use of alcohol is detrimental rather than beneficial, and that all alcoholic excesses are to be carefully avoided.

Arterio-Sclerosis.—Karl Grassmann considers the etiology, pathology, diagnosis, sequelæ, and treatment of arterio-sclerosis. Hereditary influences play a certain part in its causation. Syphilis and alcohol are prominent etiological factors. Gout, rheumatism, and various acute infectious diseases must also be considered as causes. In certain instances toxins and ptomaines ingested with food are to be held responsible for the development of this condition. In pronounced cases the peripheral arteries may visibly palpate, and have a sinuous appearance, but such may not be apparent even when a considerable degree of sclerosis is present. Among the pulse symptoms the so-called "stability of the pulse" should be especially mentioned. This is shown in that the number of radial pulsations remains the same in the horizontal as in the upright position. When this is combined with accentuation of the second heart sound it may be considered as pathognomic of the disease. Recently the Röntgen rays have been brought into play in diagnosis, and have rendered valuable service. So-called intermittent claudication is also a diagnostic symptom of value. Here marked pains, with partial loss of function, are present in certain muscles of the lower extremity upon slight exercise. If with this no pulsation can be felt in the arteries of the feet, it may be inferred that arterio-sclerosis is present. Of the many diseases for which arterio-sclerosis is at least in part responsible, diabetes mellitus should be particularly mentioned. In this disease the arteries of the pancreas are very frequently affected in the manner above described. In the treatment of arterio-sclerosis iodine takes first rank, and of its various preparations sodium iodide is to be preferred. Suitable hygienic and dietetic measures should also be instituted. Especial attention should be given to the causative factors present in each case, as only in this manner is it possible to permanently benefit the condition.

The Included Bodies in the Giant Cells of Tuberculosis.—[illegible] He holds that they [illegible]

Some Cases of Snake-bite Treated with Calmette's Serum.—[illegible] February [illegible]

Examination of the Blood in Doubtful Cases of Syphilis.—[illegible] an increase in the total number [illegible] and an increase in the density of the blood, with a tendency to a return of the normal number of leucocytes and of Bizzozero's platelets. [illegible] and the [illegible] information can be obtained by examination of the blood.—[illegible] February [illegible]

The Prevention of Death from Chloroform Narcosis.—[illegible] states that as the first source of danger [illegible] in reflex cardiac syncope, we must combat it by methods capable of lowering the general [illegible] sensibility, especially the naso-pharyngolaryngeal, and by [illegible] the moderating power of the centres in the medulla, and the excitability of the [illegible] with which they are connected. This can be accomplished by giving general and local analgesics before the chloroform is administered. As a [illegible] morphine is the most valuable, in association with atropine. [illegible] a soluble narcotic, is useful in cases where morphine is considered unsafe. Sparteine is also valuable. Local applications of cocaine to the nasal and pharyngo-laryngeal mucosa are most efficacious in preventing the arrest of heart or respiration. To combat the second danger, which is that of the toxicity of the chloroform itself, there are the various methods of artificial respiration, including rhythmical traction of the tongue.—*[illegible]*, February [illegible]

Experimental Researches in Regard to Tuberculosis Toxin and Bacilli Contained in the Spermatic Fluid of Tuberculous Animals.—Angelo [illegible] concludes that the semen may contain both the toxin and the bacillus of tuberculosis. The toxin may cause sterility in the female or [illegible]. A fetus born of a tuberculous father may die prematurely, although having no tuberculous lesions. Premature death and abortion are in direct relation to the gravity of the tuberculous process in the father at the time of impregnation. A female rabbit inoculated by a tuberculous male may die whether it has aborted or gone on to term, and the rapidity of the fatal issue also depends on the condition of the disease in the male at the time of fecundation. Tuberculous toxin injected into the vagina of the rabbit causes [illegible]. Impregnation by a tuberculous male is more dangerous as regards intoxication than in reference to tuberculous infection. Abortion and early death of the new-born animal may result from the transmission of the poison through the placenta.—*[illegible]*, February 22, 1902.

The Gastric Functions as Observed in a Patient Whose Spleen had been Removed.—Pietro [illegible] gives the following as the chief facts noted after splenectomy: (1) [illegible] and retarded digestion of albuminoids. (2) Increased and protracted secretion of HCl. (3) Absence of abnormal fermentation. (4) Retardation in the emptying of the stomach. (5) Increased activity of artificial digestion by the addition of pepsin or of splenic extract from a lamb to the gastric filtrate. (6) Absence of subjective phenomena on the part of the individual with the exception of a certain hyperexcitability of the stomach towards Ferannini's test (150 gr. of [illegible] meat [illegible] 250 gr. water), and a slight [illegible] weight. The conclusions [illegible] are that the spleen products [illegible] to the digestion of albuminoids, [illegible] influencing either the quantity or the activity of pepsin. Although the [illegible] of albuminoids is diminished, it is to a certain extent [illegible] by the compensatory [illegible] of [illegible] organs and [illegible].—*[illegible]*, February, 1902.

The Journal of Tropical Medicine, March [illegible]

Notes on the Supposed Transmission of Plague by Fleas and of Relapsing Fever by Bedbugs.—George H. F. Nuttall finds that there is no trustworthy experimental evidence [illegible] hypothesis that fleas may serve as agents for the dissemination of plague. He experimented with upwards of [illegible] fleas and bugs, but was unable to [illegible] mice and rats through their bites. Nuttall [illegible] with the [illegible] of [illegible] which had [illegible] the blood of relapsing fever patients.

Two Notes on Malarial Fever in China.—W. G. K. [illegible] gives the treatment of the disease by injections of [illegible]. In no case did he obtain a cure, [illegible] and [illegible] did not stop [illegible]. There was little [illegible] after [illegible]. [illegible] was [illegible]. He used [illegible] to [illegible]. The author calls attention to a symptom found in two-thirds of the cases in a severe epidemic of malarial fever, namely, [illegible] of the tongue [illegible], usually the left, when [illegible].

The Edinburgh Medical Journal, March, [illegible]

The Immediate Position of the Arm After Removal of the Breast for Cancer.—Thomas Carwardine is convinced that the practice of fixing the arm to the chest after this operation is a faulty one, and answerable for much of the impairment of utility and of edema of the arm which frequently ensue. The best position for the arm, in order to give wide range of movement, will be that (a) which gives the longest base to the axillary triangle, (b) which approximates the base to the apex, and (c) which prevents the tissues being [illegible] during the healing process. The abducted position meets all these indications. The author protests against adduction as being anatomically, physiologically, and pathologically wrong, and urges the universal adoption of the abducted position of the arm after removal of the breast. The apparatus is simple—a pillow on which to rest the arm, and a bandage to fix the forearm to the pillow being all that is necessary.

Post-Operative Hematemesis, with Notes of Eleven Cases.—Robert Purves says that it is clear that all cases of this affection are not due to any one cause. In some cases it may be attributed to gastric ulcer, or rupture of a vessel, [illegible] to injury, and a non-infected embolus from ligatured [illegible]. But in the majority of cases the origin is of an infective nature. The prognosis is always grave. The more marked the septic reaction is in a case, as shown by discharge from the wound and temperature, the better is the chance of recovery. Subdued or marked infection with subnormal temperature and rapid pulse, a rapidly increasing vital depression, the vomiting tending to become [illegible], all render the prognosis graver. If bilious vomiting appears *after* one or two hematemeses the prognosis is favorable. The line of treatment to be adopted is one similar to that used in cases of septicemia. Stomach washing with 2 per cent. soda solution followed by washing with a 1 to 1,000 nitrate of silver solution; in collapse infusion of normal salt solution and strychnine hypodermically.

Some Practical Suggestions for the Prevention of Malarial Fevers.—G. T. [illegible] considers the matter to be largely one of sanitation. If we improve the ventilation of native houses, the less anopheles will we find in them. If we reduce the overcrowding in the houses of native cities, the fewer [illegible] will the mosquitoes find. If we improve the surface drainage of towns, the fewer opportunities for their development will there be. Nutall has shown that anopheles mosquitoes are by no means extinct in England, and it is more than probable that malaria has become extinct in England very largely from the improved sanitary conditions of our towns and villages, and also from the better housing of the poorer classes, and it is because the sanitary surroundings of people living in Indian towns and villages is still so far from perfect that the death-rates from malaria are still so high.—*Indian Medical Record.*

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held March 17, 1902.

PARKER SYMS, M.D., PRESIDENT.

Smallpox and Its Differentiation.—Dr. CHARLES S. BENEDICT read a paper with this title. He said that it was amusing to note how the nomenclature had been modified by the frantic efforts made in certain quarters to find a diagnosis other than smallpox. It was in this way that smallpox had recently become known as "Cuban itch" and as "Philippine measles." Smallpox was often called varioloid in the hope of avoiding the correct diagnosis of smallpox with all its attendant inconveniences and penalties, but varioloid was not recognized officially, and should not be looked upon as anything more than a mild type of smallpox. The presence of a rigor, followed by high temperature, headache, angina, lumbar pain and prostration should at least lead the careful physician to search thoroughly for an eruption. Anomalies of fever were very frequent in the early stage of smallpox, and the initial fever was apt to suddenly fall by crisis. Later on the secondary fever would develop, and might be as high as the initial rise of temperature. Vomiting was frequently observed in children, and delirium in adult alcoholics. The eruption makes its appearance from twenty-four to thirty-six hours after the chill, and in fourteen days dessication occurs, and is followed by desquamation. The latter usually terminates in three weeks. The eruption was at first macular, and was completely developed in about twenty-four hours. In a general way, the intensity of the disease was in proportion to the extent of the integument involved. The macule of smallpox was dark red in color, and about one-eighth of an inch in diameter, disappearing on pressure. It was followed, in a few hours, by the hard, shot-like papule. By the sixth day the vesicles were perfectly formed, and by the ninth day they were converted into pustules. By the fourteenth day the odor of putrefaction was usually well marked. The fulminating form of smallpox was hemorrhagic, and usually terminated fatally within forty-eight hours. When the ocular conjunctiva was involved, it indicated a severe type of the disease. In making the diagnosis of smallpox it must be differentiated chiefly from varicella, measles, scarlet fever, malignant endocarditis, cerebrospinal meningitis, erythema multiforme, papular syphilides and pemphigus. In varicella umbilication was rarely if ever seen, and the shot-like feel of the smallpox papule was absent. It was only in the confluent form that much difficulty would be experienced in the diagnosis. The non-appearance of measles in the throat as a vesicle was a useful point in diagnosis. Those of considerable experience were more apt to confuse smallpox with measles than with varicella. Scarlatina might be taken for variola only in the earliest stage. The erythema of variola was of short duration, except in the hemorrhagic type, and then it did not, like scarlet fever, disappear on pressure. Two days would determine the character of the disease if a diagnosis could not be positively made at first. The mucous membranes in scarlet fever rarely, if ever, bleed, whereas this was common in hemorrhagic smallpox. Malignant endocarditis was marked by extreme prostration and a petechial rash, which, while it may suggest variola, is more apt to be mistaken for typhus fever. Dr. Benedict said that he had never noted ocular hemorrhages in endocarditis. Heart murmurs would not be of value in the differentiation, but the duration and course of the disease would lead to the correct diagnosis. Septicæmia following abortion and accompanied by streptococci in the blood might be mistaken for hemorrhagic smallpox, because of the hemorrhages under the skin, but the affection, being of longer duration, would usually lead to the correct differentiation. The differential diagnosis of erythema multiforme of Hebra from smallpox would not usually be required except in the early stages. A papular syphilide was sometimes a cause for anxiety in a smallpox epidemic. The appearance of the lesions in pemphigus and the absence of constitutional disturbance should prevent its being mistaken for smallpox. Vaccinia was frequently seen in vaccinated infants, being transferred from the vaccinal vesicles by the fingers. The individual lesion more nearly approximated that of variola than any other disease, but, of course, the lesions were scanty and the duration of the disease only nine days. The perfection of the lesion in vaccinia served to distinguish this affection from a mild type of smallpox. Pemphigus contagiosa could be diagnosed usually by the large elliptical crusts, occurring chiefly on the back of the neck, the buttocks and feet. In the early diagnosis of smallpox no one symptom or sign should be implicitly relied upon. While the eruption was the main guide to the diagnosis, the constitutional history must not be disregarded. Even the most expert diagnosticians were often unable to make the diagnosis immediately.

Smallpox and Its Treatment.—Dr. S. DANA HUBBARD read this paper. He said that at the present time the indications were that the cause of smallpox would soon be found, and if this were the case it was reasonable to suppose that greater success in the treatment would follow. Early isolation was, of course, most important, and should be the rule in all hospitals; indeed, in these institutions an excellent preventive of contagious disease was the provision of a reception ward, in which all new patients are kept for about two weeks. During this probationary period it was advisable to keep visitors away. In transferring a patient from his home he should be wrapped up, head and ears, in blankets. As neglect and filth usually lead to the direst results, any old shed was by no means suitable for a smallpox hospital. The surroundings should be as aseptic as possible. The wards should have a temperature of 70° to 78° F., and should be ventilated in such a way as to avoid draughts. Smallpox renders the mucous membranes very sensitive to draughts of cold air, and bronchitis and pneumonia are very likely to follow such exposure. Pneumonia was exceedingly fatal in persons sick with smallpox. A large, loose gown, rubber shoes, rubber gloves and a cap constitute the outfit to be worn by the person entering a room occupied by a case of smallpox. The fumigation of the room after the removal of the patient should be done in connection with moisture, and, if properly done, the fumes at the completion of the process would be so dense in the room that one could not see through them a distance of more than four feet.

Treatment.—The smallpox patient must be kept scrupulously clean, and the floor must be swept at least once daily after having been sprinkled. The attendants should be clothed in washable goods and canvas shoes, and should change the clothing and wash their hands of patients outside of the sick-room. The patient should receive a daily sponging. For the backache of the first few days it was well not to make use of counterirritation, because this causes a profuse eruption to develop in a very uncomfortable situation. The headache could be easily controlled by acetanilide, soda and caffein. The thirst should be quenched by the free use of water, lavender water, or ice and lemon juice. After the bathing the application of alcohol was usually refreshing, but if there was much itching it should be avoided, and instead the surface should be well rubbed with carbolized oil of a strength of 5 to 20 per cent. After the bath a pleasant application was a powder composed of subnitrate of bismuth, lycopodium and starch. The water used for bathing a smallpox patient in the stage of suppuration should contain from half a grain to two grains of permanganate of potassium to the ounce. In this stage of the disease it was also advisable to give quinine internally, but these patients would be found unusually sensitive to this drug, so that it must be given in small doses. The treatment of smallpox more closely resembled the treatment of typhoid fever. In septic cases alcoholic stimulants should be given with a free hand. In this connection it was well to remember the advice given to a well-known physician regarding the use of whisky in septic cases: "Don't let them die sober." The eyes should be frequently flushed with boric acid solution, and if there was much swelling of the lids cold sponges should be applied frequently. A mild alkaline mouth wash should be used to keep the mouth clean, and the tongue cleaned off with a softened scraper. The skin required constant attention throughout the disease. During the vesicular and pustular stages an effort should be made to prevent rupture of the lesions. Wet applications should be [illegible] of lint and [illegible], when the crusts form, on. Very sick patients should be separated from convalescent ones. Very little had been accomplished at the present day in preventing the pitting. He was of the opinion that if secondary infection could be prevented, pitting would not occur. The nearer one approached to asepsis, the better would be the result in this regard. The too early removal of the crusts should be prevented. A mixture of boric acid and glycerin applied constantly under a mask had acted very well. After convalescence the body should be thoroughly scrubbed and disinfected, and the hair [illegible] out. The patient should then go to another room and take a bath of bichloride of mercury solution. The following day this bath should be repeated before putting on his own [illegible] clothing.

What Constitutes Efficient Vaccination?—Dr. Frank S. Fielder read the paper. He defined efficient vaccination as that which assures to those vaccinated (1) The smallest proportion of smallpox cases per thousand individuals, (2) The longest duration of immunity among those who finally take smallpox, (3) The lowest mortality among those who contract the disease, and (4) The mildest course of the disease and the least amount of subsequent pitting in those who, having had smallpox, survive it.

Character of the Scar.—For several months after a successful vaccination the normal scar is red and usually depressed. After several years it is whiter than the surrounding skin and regular in outline, the edge being well defined, and the entire area slightly depressed with a smooth or slightly striated center. It is surrounded by a more or less deeply foveated ring. This ring corresponds to the area of active granulation, and the center either to the original area of scarification or to the cicatrix following the separation of a more or less deep central slough. The shape of the scar depends upon the shape of the scarification, while its size depends partly upon the scarification and partly on the activity of the virus. Sometimes the scar is poor even when the vaccination has run a well-marked and typical course, but, as a rule, a good vaccination gives a good scar.

Number of Insertions.—The speaker said that the number of insertions to be made at one time was a mooted question. Unfortunately there was not much recent literature in this country on this subject, because it had been the custom here for physicians to vaccinate in one spot only. Dr. E. C. Seaton and Dr. Buchanan had made observations during a smallpox epidemic in London in 1863 on more than [illegible] persons. Some of these had never been vaccinated, but most of them had been vaccinated in various manners and degrees. There were [illegible] per thousand who had been marked with smallpox but had no vaccination scars, while of those having one vaccination scar there were 6.8; of those having two scars, 1.5; of those having three scars, 1.4; and of those having four or more vaccination scars 0.67 per thousand had been marked by the disease. As to the quality of the scar, those with "bad" scars represented 7.6; those with "tolerable" scars, 2.35, and those with "excellent" scars, 1.22 per thousand. These tables show, therefore, that among more than fifty thousand persons examined, the smallest proportion of smallpox cases per thousand was found in those who had been vaccinated in four or more spots and presented scars of excellent quality. These observers also found that the better vaccinated persons showed less pitting than the poorly vaccinated ones when taken ill with smallpox.

Duration of Immunity.—With reference to the duration of immunity to smallpox following different methods of vaccination, Dr. Cory made observations between 1884 and [illegible] on 448 persons who were attacked by the disease. Of the 448 vaccinated persons the average age was [illegible] of years. Of the [illegible] alleged to have been vaccinated, but exhibiting no scar, the average age was [illegible] years; of the 47 vaccinated persons having one scar the average age was [illegible] years, while of the 31 showing two scars the age was 17.8, and of the [illegible] showing four scars, [illegible] years. This table, although dealing with too small a number of cases for positive conclusions, seemed to show that vaccination by multiple insertions gives slightly longer immunity to smallpox than the single method. Again, Gayton, in the papers of the Royal Commission on Vaccination, collected [illegible] the following table upon 7,114 cases of post-vaccinal smallpox. Among the [illegible] cases showing one scar the percentage of deaths was 3.4; among the 2,464 showing two scars, the percentage was [illegible]; among the 1,434 showing three scars the percentage was [illegible], and among the 1,[illegible] showing four scars the percentage was [illegible]. This table pointed strongly to the conclusion that vaccination by multiple insertion gives better protection than a single insertion. J. F. Marson, for more than thirty years the resident physician of the London Smallpox Hospital, had made very careful observations on the number and quality of the scars in all the cases of post-vaccinal smallpox which had come under his care. From [illegible] to 1861 [illegible] cases of smallpox had been treated in the hospital. Of these, [illegible] showed no marks. About 50 per cent. of the patients admitted with smallpox had been previously vaccinated in some way. Among those who had never been vaccinated the percentage of deaths was 35.5; among those alleged to have been vaccinated, but showing no scar, the percentage was 21.7; among the 1,357 showing one scar, the mortality was 7.5; among those showing two scars it was 4.13, and among 268 showing four or more scars the average was [illegible].74. From 1852 to 1867 Marson had continued his observations in treating [illegible] cases. Of those never vaccinated, the percentage of deaths was 34.0; of those alleged to have been vaccinated, but showing no scar, it was 30.5; among those showing one scar it was 13.8, and among those showing four or more scars this percentage was 0.9. Marson concluded that the efficiency of the vaccination was in exact ratio to its excellence and completeness, as shown by the number and quality of the resulting scars. W. M. Welch, who for twenty-five years had been in charge of the Philadelphia Smallpox Hospital, from a similar study of his cases, confirmed Marson's view that the protective degree of vaccination could be measured to a considerable extent by the quality of the scars. Among 2,415 persons showing one vaccination scar the percentage of deaths was 18.46, among 5[illegible]3 showing two scars it was 11.[illegible], and among 420 showing four or more scars it was 10.4[illegible] per cent. This table showed that one good vaccination scar protected better than two, three or four fair or poor scars. Welch concluded that the quality of the scars was a far more reliable indication of the degree of the protection than the quantity, and that when the scars were typical it made no difference whether they were single or multiple. However, on comparing the total number of cases vaccinated by the different methods his own table showed that the mortality of one-scar cases was 18.46 per cent., while that of the cases showing four or more scars was 10.4[illegible] per cent. From the above evidence, Dr. Fielder said it seemed fair to conclude with Marson that "test the question in whichsoever way we will, the result is in favor of producing four vesicles at least at vaccination with lymph which leaves good, permanent cicatrices."

Dr. JOHN H. BRANTH spoke of the old practice of inoculation against smallpox or "engrafting." He expressed the opinion that in England and, particularly, in Ireland, the great epidemics had been influenced to some extent by this factor, and raised the question as to whether it might not be safer to inoculate at a time when no epidemic is raging. It was certainly reasonable, he thought, to assume that during an epidemic the majority of the population was in a highly receptive condition for the virulent and unmodified form, if not protected, otherwise no epidemic could occur. In discussing the nature of the protection afforded by vaccination, the speaker, by way of illustration, referred to a very recently published article by Ernest Hutchinson, D.V.S., of Portland, Ore., a U. S. inspector of Animal Industry, in which it is stated that the tubercle bacilli from one species cannot be transplanted with the same success to other species, and that if successful a modification of virulence occurs. Dr. Branth said that "the grease" in horses, which occurs near the hoof, is said to give the same protection as cowpox vaccine. In the human being the epidermis and the involuted respiratory tract and the alimentary canal seemed to be the most vulnerable parts. He suggested that vaccina might be due due to modified virulence, such as claimed by Hutchinson tuberculosis for different species. The arm-to-arm vaccina "takes" in about four days, while cowpox vaccina "takes" in a longer time generally. The speaker then quoted the recent statistics of London, where compulsory vaccination laws had been relaxed. A report for one week, taken at random, showed that there were more than 500 cases of smallpox in London that week, while in all Prussia, where strict laws regarding vaccination are in force, there were only four cases. The antivaccinationists claimed that compulsory vaccination is an infringement of the personal liberty that should not exist in our free country, but, on the other hand, he would claim that the presence of an unvaccinated person is an infringement on his own personal liberty, being a danger to his well-being.

Smallpox in Cuba.—Dr. WILLIAM DOLZ referred to 1,300 cases of smallpox that he had isolated on the northern coast of the province of Santiago, and had treated on the plan sketched by Dr. S. Dana Hubbard. They were bathed with bichloride solution, 1 to 5,000, once, twice or three times a day, according to the intensity of the eruption; the worse the eruption, the more frequent the bathing. Half of the cases were confluent, two-thirds had not been vaccinated, and the conditions for treatment were anything but favorable. Allowing for this, the death-rate of 10 per cent., he thought, was a good showing. A smallpox epidemic had been sweeping over the country for over a year, and over 4,000 people had succumbed to the disease; yet in ten weeks the 1,300 persons isolated were discharged. In addition, about 10,000 persons were vaccinated. It was a most significant fact that, although three years had elapsed since then, no new case of smallpox had developed in that district.

Vaccination Immunity Sometimes Very Short.—Dr. DAVID P. AUSTIN objected to the hospital statistics quoted by Dr. Fielder. He said that in Germany, and in some other countries, the primary vaccinations were made in three or four places at the same time, and hence, in a subsequent investigation, all of these scars would count. Two vaccinations, made at different times, he claimed protected more fully against smallpox than one vaccination consisting of several simultaneous insertions. Dr. Austin then referred to 10,000 vaccinations made in the public schools of this city by himself, of which records had been kept. Of this number, between 60 and 65 per cent. resulted in a successful vaccination. It was found that among the cases that had been vaccinated only once previously, between 40 and 50 per cent. of successes were noted, whereas those who had been vaccinated four or five times previously yielded only 8 or 10 per cent. of successes. One vaccination should not be relied upon for protection for any length of time. Growing experience convinced him that immunity was more dependent upon the repetition of vaccination than upon the number of scars produced. Within three months it had been his fortune to encounter several persons who had been vaccinated in Germany by five simultaneous insertions, and who had developed varioloid in this country subsequently. One of these individuals had had varioloid twice. The speaker said that, in his opinion, immunity was that condition which protected the person from smallpox for the balance of his life. In some individuals it was necessary to repeat vaccination four or five times before this immunity was secured, but when once secured, this lasted for life. There was no foundation for the old notion that partial immunity lasted for seven years, and that, therefore, vaccination need not be repeated more frequently than once in seven years. To test this question, Dr. Austin said that on a certain day he had vaccinated ten children at his office, and all of them successfully. One month later he had vaccinated them all again, and in eight of them this second vaccination was successful. In another month six of the children were again vaccinated satisfactorily. Six of the children were vaccinated a fourth time, with four successes. This series seemed to prove the truth of his statement, that one vaccination must not be depended upon for any length of time.

Immunity to Smallpox and to Revaccination Not the Same.—Dr. FIELDER said he thought it was generally admitted that two vaccinations done at different times were better than several insertions made at the same time. He was himself a firm believer in revaccination, but it was desirable to make each vaccination protect the person for as long a time as possible, so that if the person neglected subsequent vaccination he would be protected for the maximum time and the community likewise. He wished especially to call attention to the fact that immunity to smallpox and immunity to revaccination are not the same—in other words, that a person might be immune to smallpox and might yet be successfully revaccinated. A case in point was that of the resident physician on North Brother Island, who, in the midst of smallpox cases in the hospital, and without contracting that disease, was able to revaccinate himself successfully. The reason for this difference in immunity might, perhaps, be found in the fact that ordinary contact with smallpox cases was not so great an exposure as the actual introduction of the vaccine virus into the system. Dr. Fielder said that he, too, had performed experiments somewhat similar to those detailed by Dr. Austin, but he was surprised that Dr. Austin had repeatedly obtained such a large proportion of successes after such short intervals. He knew of no rule by which one could judge of the length of time a person would remain immune; nevertheless, among those vaccinated, the longest immunity and the least mortality, if smallpox occurs, would be found among those who had been vaccinated in several places at one time.

A Case of Tuberculosis of the Skin Following Accidental Inoculation with the Bovine Tubercle Bacillus.—Mazijck P. Ravenel reports the case of a physician who, while performing autopsies on two cows which were the subjects of experimental tuberculosis, slightly wounded the flexor surface of his wrist. The wound was merely washed in water and healed promptly. Four weeks later, the scar was seen to be red, prominent, and sensitive; it increased in size rapidly, and about two weeks later there was a nodule 15 mm. long by 8 mm. wide. This was removed. and with a portion of it two guinea-pigs were inoculated subcutaneously, and both developed generalized tuberculosis. Another portion of the nodule was examined. microscopically, and showed a large number of giant cells and tubercle bacilli.—*University of Pennsylvania Medical Bulletin.*

NEW YORK PATHOLOGICAL SOCIETY

Regular Meeting, Held at the Academy of Medicine, February 12, 1902.

JAMES EWING, M.D., PRESIDENT, IN THE CHAIR.

Carcinomatous Ulceration of Duodenum, with Abscesses of Liver and Pancreas.—DR. J. H. LARKIN, in presenting this case, said that for several years the society had been receiving reports on perforating ulcers of the duodenum, but the present case was of exceptional interest because of the complications disclosed by the specimen now exhibited. He had to apologize for the incompleteness of the history of the case.

The patient was a woman forty-six years of age, an Italian, and it was difficult to obtain any facts beyond this, that for about two months she had been ill, mainly with pains in the lumbar region. No physician had seen her until two weeks previous to her being admitted to the hospital. At the time of her admission the case was put down as one of ordinary destitution and starvation. Three hours before death she had a large and copious bloody movement from the bowels, then went into a collapse and died. At the autopsy an interesting condition of the organs was revealed, but before speaking of this, he wished to say a word about the symptoms. At no time, so far as could be ascertained, had there been any abdominal pain or vomiting. At the autopsy he found the body markedly emaciated. There were no evident signs of peritonitis, some clear serum in the abdominal cavity; all the viscera were normal, except that they were pale and blanched from loss of blood. The sudden hemorrhage and collapse pointed to an intestinal lesion. He expected to find an abdominal aneurysm with perforation into intestine, but in this he was mistaken. In the stomach there were two pints of clotted blood, but the mucous membrane was perfectly normal. On going down to the duodenum he discovered a large, irregular ulcer, about the size of a dollar, with several small nodules at the periphery. In the center was a large necrotic mass directly through the duodenum, and the adjoining liver tissue was extremely necrotic, making a large abscess cavity filled with pus and recently coagulated blood. In the middle of pancreas was a small metastatic nodule, firm and fibrous. The blood vessels were dissected up and the superior mesenteric vein found necrotic and leading directly into the abscess cavity. Microscopical examination of sections taken from edge of ulcer in duodenum and mass in pancreas showed adenocarcinoma.

Acute Case of Gangrenous Appendicitis Without Indications for Operation.—By DR. SAMUEL EVANS. (Vide page 486.)

Carcinoma of the Pancreas. Specimen presented by DR. A. E. THAYER. The clinical history dated from five weeks before the patient was admitted to the hospital. At that time he began to have severe pains in the lumbar region, which radiated forward into the abdomen, was partially relieved by pressure, and lasted half a day. Such attacks occurred at intervals until admission. He vomited at times, but there was no blood in the vomit. His strength and flesh had steadily diminished, and for about three days he had been jaundiced. His feces had been formed and yellow.

On admission the patient was poorly nourished, respiration was wholly thoracic; the abdomen was tense, retracted and generally tender on palpation, and in the epigastrium and reaching into each hypochondrium there was a prominent mass of irregular outline. Neither liver nor spleen could be made out. The urine contained no albumin nor sugar, but was bile-tinged. The entire surface was deeply jaundiced.

Patient's temperature varied between 99° and 101°, respiration about 28 to 30, and pulse 120 to 130, while he was in the hospital. An exploratory operation was performed, and from that time he sank, having diarrhœa, and vomiting a dark fluid, till he died from exhaustion, about three weeks after admission.

At the autopsy there was found a large mass in the pancreas, the [illegible] portion about [illegible] of its length showing cystic softening, and involving the spleen and the left adrenal. The lymph nodes about the ducts were generally involved. On the upper posterior aspect of the liver there was a [illegible] metastasis, which had nearly penetrated a large branch of the hepatic vein. The [illegible] contained bluish gray fluid; the gall-bladder was a little distended. There was no dilatation of the stomach nor constriction of the duodenum. On microscopic examination the tumor was found to be an adenocarcinoma. No trace of pancreatic tissue was left, and almost no splenic.

Dr. THAYER presented also a case of suppurative cholangeitis due to biliary calculi impacted in the common duct. There was no clinical history. The patient, a Russian of about forty-five years, was intensely jaundiced and much emaciated. Post-mortem six gall stones were found impacted in the common bile duct, lying in a collection of pus. All the larger branches of the bile ducts through the liver contained pus and small grains of black pigment, and in the left lobe there were several abscesses, about 3 to 4 cm. in diameter. The gall bladder was much distended, contained grayish green, thickened mucous fluid and grains of pigment, and from its inner wall there grew a small soft fibroma. There was no distention of the pancreatic duct, no interstitial pancreatitis nor fat necrosis. There was complete hyperplasia of the left kidney.

The two cases were of interest as showing how little reliance can be placed in Courvoisier's law, so-called: that with bile stones the gall-bladder is small, and with malignant disease of the common duct it is large. A number of recent cases demonstrate that this view is untrustworthy. The relation between occlusion of the common bile duct and pancreatitis and fat necrosis also appears to be slight from these cases. Further, in each there might have been sugar in the urine, especially in the first case, where the pancreatic tissue was wholly replaced by a neoplasm, but, so far as the records show, there was none.

Dr. F. C. WOOD reported two cases of lymphocytosis simulating leukæmia. One was that of a small child with a tuberculous lesion of the hip, the lymphocytosis disappearing after drainage of the abscess; the other was a fatal case of anæmia without lesions in the bone marrow. Both cases will be reported in detail later.

The President said that these cases were important additions to the scanty knowledge which existed on this subject, and showed the importance of examining other things besides the blood before accepting a diagnosis of lymphatic leukæmia. One feature of extreme interest in the second case was its resemblance to pernicious anæmia. At the same time it differed so much from the reported cases of pernicious anæmia without bone marrow changes, that he would hesitate to accept it as such without study of all the antecedents.

Complete Double Ureter on Each Side, Pervious Througbout.—DR. T. C. JANEWAY, in presenting this specimen, said he need not detain the society with any lengthy description, as it was simply a very rare anatomical abnormality. In looking over the transactions of the London Pathological Society and *Virchow's Archiv*, he had found only one exactly similar case, reported by Ewart. Specimens showing ureter double for a portion of its length on one side, and on the other side one normal ureter and one abnormal one emptying into neck of bladder or prostatic urethra, have been encountered by Weigert, Hoffmann, Tangl, and Wood. Double ureter on one side only seemed a much more common condition, cases having been reported by Weigert (seven in one year), Thompson, Durham, Kelly, and Voelcher. This specimen came from a middle-aged woman, who had died of chronic diffuse nephritis. It shows the separation of the pelvis of the kidney into two distinct cavities, common to all previous cases, but is unusual in that there is no crossing of the ureters, and that the upper ureter in each side opens above the lower in the bladder, the opposite of Weigert's findings.

Dr. **Warren Coleman** and B. H. **Buxton** presented a paper on "Paratyphoid Infections."

Gilbert proposed the terms "paratyphoid" and "paracolon" in 1893, to designate the intermediates of the typhoid-colon group of bacilli. Durham calls the intermediates the "Gaertner group." The group includes Bacillus enteritidis, Bacillus psittacosis, Bacillus paratyphosus, Bacillus choleræ suis, and some others.

The intermediates are pathogenic for man, Bacillus enteritidis producing epidemics of meat-poisoning, Bacillus psittacosis, a peculiar epidemic broncho-pneumonia with typhoid symptoms, and Bacillus paratyphosus, a disease closely similar to typhoid fever.

Attention is confined in our paper to paratyphoid fever. Thirteen cases have been reported in whose blood, stools, urine, or complicating inflammatory processes paratyphoid bacilli have been found. Four cases have been reported in whom the diagnosis was made by the serum reactions. We report a fourteenth case, clinically identical with typhoid fever, in whose blood a paratyphoid bacillus was found.

An analysis of the symptoms of the reported cases shows that the disease closely resembles typhoid fever. All the cases were regarded as such until a bacteriological examination revealed their true nature. None of the cases gave the Widal reaction, and it is thought that other cases of clinical typhoid fever which have failed to give the reaction may have been paratyphoid fever.

Bacteriologically, the bacillus isolated from the case closely resembled Bacillus typhosus in many biological characters, but produced gas in glucose media.

Dr. N. E. **Brill**, in discussing the paper, said he would like to say a few words in reference to the clinical aspect of the subject. About five years ago he called the attention of the medical profession to a group of cases which clinically bore some resemblance to typhoid fever, but in which the Widal reaction remained persistently absent throughout the disease and the subsequent convalescence. There could be no doubt about the absence of the Widal, as examinations were made every day of each patient, not only during his stay in the hospital, but after he had left. At that time, he said, he was impressed with the specificity of the Widal reaction, and on that account he attempted, as far as his resources permitted and the facilities of the laboratory at Mount Sinai Hospital afforded, to determine the cause of the infection in the seventeen cases of this class which came under his observation. He said it should be remembered that at that period, outside of Elsner's and Hiss' media, no differential method of culturing the Eberth bacillus had been suggested, nor had any attempts been made to differentiate the organisms whose biological situation was intermediate between the typhoid bacillus at the one side and the colon bacillus at the other. The bacteriological work, therefore, while it was serious, could not be taken, when viewed in the light of present methods, as very reliable. It was sufficient, however, to prove that in the feces and in the blood aspirated from the spleen—a procedure which he would not now countenance—of the cases reported by him the typhoid bacillus was absent. A bacillus answering to the ordinary tests of the colon bacillus was isolated. At that time, bearing in mind the specific nature of the Widal test, they tried the reaction of the blood in each of the seventeen cases with a culture of the isolated bacillus, but failed to get a reaction. In two of the cases the effect of the blood of the patients upon a culture of the bacillus obtained from each patient respectively failed to give a reaction. This showed that the speaker appreciated the fact that some other organism than the one isolated was the offending and disease-producing organism. The bacteriological work was finished before he read of Widal's observation of a paracolon bacillus from an œsophageal abscess which had casually come into the hospital in Paris. There was no clinical observation in the case of Widal's, as he reremembered.

When he presented his paper based on the examination of these seventeen cases, Dr. Brill said, he insisted upon the view that these patients did not suffer from typhoid fever, but from some other infection. One of the strongest factors which induced him to form this belief was the fact that a nurse at the training school at the hospital had had an undoubted typhoid six months before with a Widal reaction, and became ill again after six months with an infection which clinically was similar to the first, but in which the Widal reaction was persistently absent, and in whose aspirated spleen blood no typhoid bacilli could be found, but a bacillus which they, at that time, regarded as the ordinary colon bacillus.

He said his view of the presence of another than the typhoid infection was bitterly assailed, and in speaking of the cases with Dr. Osler, the latter regarded them as typhoid. Shortly afterwards, Norman B. Gwyn, of Johns Hopkins, published a case which was similar to those which Dr. Brill had previously reported, and from whose blood Gwyn isolated a paracolon bacillus. The speaker said from this time on (from 1898) he had insisted at various societies that his cases were not cases that should be classified under the head of typhoid fever, but that they were most probably the result of a disease due to a paracolon infection. The expression of this view always called forth opposition, and it was only three months ago that the worthy President of this Society, Dr. Ewing, fiercely assailed it on an occasion when typhoid fever was the subject for discussion at a meeting of the New York County Medical Association; at which meeting Dr. Brill had again called attention to the fact that some cases reported as typhoid were not typhoid, but might probably be a disease due to a paracolon, or, as the reader of the evening called it, following Schotmüller, a paratyphoid infection.

In conclusion, he wished to say that clinically, as he had shown his paper nearly five years ago, these cases could be readily differentiated from typhoid, notwithstanding they so closely resembled that disease. Under all circumstances he contended that he had the right to claim priority for himself in clinically calling attention of the medical world to the possibility of some cases like his own being not a typhoid but a paratyphoid infection, and in accurately describing these cases.

He did not believe that his reported cases were of a solitary epidemic, because since then, and almost every summer, he had met with identical cases, and at that very moment two cases were in the hospital with a most probable paratyphoid infection.

Dr. E. **Libman** drew attention to a few points to show that the subject was by no means a simple one. On a previous occasion, this matter being under discussion, Dr. Meltzer had thrown out the suggestion that in some of the cases referred to there might have existed a mixed infection; cases in which an infection by a paracolon bacillus was followed by an infection by the typhoid bacillus. In connection with this, Dr. Libman referred to a case he was studying in which it was very probable that the reverse had occurred. In his case a paracolon bacillus was isolated from the blood twice during life and from the organs post-mortem. Typhoid bacilli could not be found, but the blood of the patient a few days before death gave a positive reaction with the typhoid bacillus in a dilution of 1–250.

The blood gave a thread reaction, so-called, with the paracolon bacillus in dilution of 1–20. Dr. Libman referred to the necessity of watching for this reaction at an interval of four to twenty-four hours after making the test.

He thought it highly probable that there were cases in which the infection by the paracolon bacilli was of a secondary character.

The **President** said that Walker's experiments in Tavel's laboratory would lead one to believe that unless sera were extremely potent and the dilutions very high they failed to produce the desired results. Dr Coleman had spoken of the necessity of using different cultures in the differentiation of typhoid species. He had attempted for two months to get the Widal reaction in supposed cases of paratyphoid, but had met with no success which would lead him to the routine use of multiple cultures. He believed that the ideas on this subject would be better correlated if they retained the term typhoid in all these cases, and at the same time recognized that the bacterial causes of typhoid fever were more diverse than had heretofore been supposed.

Dr M. Manges commented on the distinctive characteristics of these cases of paratyphoid, chief among which seemed to be the rather abrupt onset and termination, the short course, the absence of abdominal symptoms, and failure to respond to the Widal reaction. He believed that a further study of the subject would lead to a simplification and perhaps to the change of some of their views in regard to typhoid. He did not think these cases of paratyphoid infection could be distinguished clinically from true typhoid as Dr. Brill seemed to think. Dr Manges regarded the differential diagnosis as very difficult, at least in his own experience.

Dr Charles Norris thought the term paratyphoid was a very poor one to use, and in adopting it they were making the same mistake as their forefathers did when they first used the term "typhoid fever." The group of bacilli giving rise to diseases resembling typhoid was a very large one, including many different varieties, from the hog cholera bacillus downward; but it was becoming the custom to recognize nothing as typhoid except that which had the specific bacillus known as the cause of the disease and bearing the same name. Further confusion had been caused by two or three different names having been given to probably the same microörganism.

Dr S. J. Meltzer said he was in some respects perhaps responsible for the name paratyphoid which had been applied to these cases; and he thought that at present it was the most appropriate term that could be used, inasmuch as the clinical symptoms resembled those of typhoid, and one could not very well employ the word paracolon, because there was no class of diseases known as colon diseases.

Dr Coleman, in closing the discussion, repeated that the reason for calling the cases paratyphoid was that they bore such a strong clinical resemblance to typhoid.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 20, 1902.

Robert F. Weir, M.D., President.

Operations for the Relief of Paralytic Deformities with Special Reference to Tendon Transplantation.—This was the subject for the evening's discussion, the meeting being in charge of the Section on Orthopedic Surgery.

Introduction; History; Indications for Operation.—Dr Royal Whitman read the opening paper. He said that the operations under discussion were intended chiefly to relieve the deformities following anterior poliomyelitis, and as in 80 per cent of these cases the lower extremities were the parts involved, the operations were ordinarily done upon the lower extremities. The first operation of this kind was done in 1882, and although the operation had now been known for twenty years, the first half of this period had been a dormant one. Two years should intervene between the onset of the paralysis and the operation. The real value of these operations had not yet been determined, for many of the cases had been reported within a few months after the operation. The field of the operation in the upper extremity was limited, it being almost impossible to restore the complicated functions of this region. The standard by which to test the result of the operation was normal function, and from this standard one must conclude that the operation is palliative rather than curative, and in most instances will supplement rather than supplant mechanical treatment. Arthrodesis was introduced in 1882, originally for the purpose of enabling the patient to dispense with a support. The field of this operation was very limited. Even at the ankle, where the operation was of the greatest service, some support would usually be required. In certain cases it might prove useful at the elbow or at the wrist joint. As a rule, the operation should only be done in late childhood or early adult life.

Deformities Due to Muscular Paralysis; Method of Production; Possibilities in Tendon Transplantation; Combinations that have been made to Correct Deformity.—Dr Walter R. Townsend read a paper with this title. He said that the original lesion did not produce deformity, but only a loss of power, a fact which, if generally understood and appreciated, would lead to early and appropriate treatment for the prevention of deformity. Gravity was the prime cause of deformity, though the action of the non-paralyzed muscles, the arrest of development of the muscles and other adjacent tissues, and the weight of the body applied to weakened structures, were important contributing factors. In paralysis of the tibialis anticus and extensor longus digitorum the foot assumed the position of equinus. Paralysis of the peronei produced talipes varus. Paralysis of the interossei and flexors of the toes produced the so-called "claw foot" by the unopposed action of the extensors. When the extensors of the wrist were affected the flexors shortened and produced drop wrist. Paralysis of the flexors of the hand was followed by extension of the hand, but as this action was limited, practically no deformity followed. A large muscle like the tendo Achillis might be easily deprived of part of its power, and that force utilized for the purpose of transplantation better than in the case of a weaker muscle. The transplanted muscles must be made to act in approximately normal lines. The author believed that in the operation of tendon transplantation there were great possibilities for good. In cases of drop wrist he would suggest that instead of cutting off all of the tendons, it was better to resort to the method of lengthening the tendons in addition to the transplantation.

Technic of Operation; Results at the Hospital for Ruptured and Crippled.—Dr Virgil P. Gibney presented this paper. He said that the first operation had been done in that hospital in 1896 on a child of ten years who had had an attack of anterior poliomyelitis when one year old. When last seen, six months after the operation of transplantation, a little valgus still remained, and although the result was fair, the muscles were quite weak. Since this time ninety-two similar operations had been done. The technic employed there differed from the ordinary one chiefly in making the incision along the vertical axis of the limb. Primary union was, of course, essential for the success of the operation. The pinching of tendons with forceps or pulling or pressing upon them should be most carefully avoided; the tendons should be handled with bits of gauze in order not to injure them. The live tendon should be transplanted into the point of attachment of the lifeless one. After the tendon had been transferred a test should be made of the position of the foot before closing the wound. His preference was for silk for suturing the tendons. On one or two occasions on which silkworm gut had been used it had been necessary to remove it through a fistula some weeks afterward. After the operation the foot should be placed in an overcorrected position and maintained there by means of plaster of Paris. In the majority of cases it was necessary to keep the limb in mechanical apparatus for many months.

Summary of Results.—Of the 92 operations, 63 had been traced. Of the latter, the results were good in 32, fair in 44 and negative in 24 per cent. The cases traced yielded the following results: Equinus, 8 cases, 1 good, 6 fair and 1 negative; 15 equino-varus cases, 4 good, 5 fair and 6 negative; 19 equinovalgus cases, 8 good, 10 fair and 1 negative; 12 calcaneovalgus cases, 7 good, 4 fair, and 1 negative; 3 valgus cases, 1 good, 1 fair and 1 negative; 1 case of calcænus with fair result; 5 cases of "dangle leg" with 5 negative results; 1 deformity of the thumb with negative result; 5 cases of drop wrist, 1 good, 2 fair and 2 negative results.

Neurological Questions Involved in Tendon Transplantation.—Dr. Joseph Collins read this paper, prefacing his remarks with the statement that the prognosis in anterior poliomyelitis should be better than it is. He said that the fact that a flexor tendon, when transplanted into an extensor, gave rise to extension, had caused much speculation as to the modus operandi, but, in reality, the explanation was quite simple. It was easily understood by an illustration of the starting of a nervous impulse from the nervous centers. A locomotive, leaving a union station, would go to either Boston or Buffalo, depending upon the track upon which it was switched, and the fact that it had been accustomed for many years to go to Boston did not interfere in any way with its going to Buffalo, provided it was shunted upon the proper track. The psychology of this subject was illustrated by two original and interesting diagrams,

Dr. Reginald H. Sayre said that in one or two of these operations that he had performed there had been more power gained than had been anticipated, but in other cases the result had been fair, or even disappointing. In some instances, the result had been better after three or four years than immediately following the operation.

Dr. T. Halsted Myers said that it was especially interesting to note that no bad results had been recorded after the operation. He would like to know whether in the operations on the arms any motions had been lost by destruction of the flexors.

Dr. B. Sachs said that the operation was a thoroughly rational one, and it seemed to him to be as fully applicable to the cerebral spastic cases as to the flaccid spinal cases. The problem in all of them was a very simple one, and consisted in diverting the force from the overacting to the underacting muscle. The operation opened up a very promising field, and was a great improvement on all previous treatment.

Dr. Henry Ling Taylor said that this evening's discussion had been a very fair and temperate presentation of the subject, which was particularly fortunate, for tendon transplantation was only now being tested. Some persons, despite this fact, had already gained an exaggerated notion of its value.

Dr. Jacob Teschner said that he had been treating many cases of anterior poliomyelitis of many years' duration on the principle that one should endeavor to build up the muscles to the highest possible point first, and then, if necessary, operate. In carrying out this method, he had found that many cases, even of fifteen or twenty years' standing, did not require operation. In an article published by him in 1895, he had stated that some of the affected muscles would act if aided by the other muscles. His experience showed him that the reaction of degeneration in a muscle proved only that some portions had undergone degeneration, and did not necessarily mean that all the fibers had been destroyed. By the treatment alluded to, the weak and helpless muscles were practically regenerated and brought under the influence of the will.

Dr. Russell A. Hibbs said that tendon transplantation had been performed in about 150 cases at the New York Orthopedic Hospital. Although the ultimate results had not been so good as the immediate ones, the operation seemed justifiable, for it made apparatus more effective, even though not supplanting it. The operation, in other words, would probably prove to be an adjunct only to mechanical treatment.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held March 4, 1902.

Joseph Collins, M.D., President.

A Case of Myotonia.—Dr. J. Ramsay Hunt presented a man twenty-eight years old, who had come to the clinic with a history of having a peculiar stiffness of the hands and of the muscles of the jaws in the morning. On awakening it was found impossible to open the eyelids to their full extent for a minute or more. This myotonia was aggravated by cold or prolonged rest. There was a consolidation at the apex of one lung in this patient. Strong, stable galvanic applications produced no wave-like contractions such as are sometimes observed in myotonia. The hands were weak; the knee jerks were difficult to elicit except on reinforcement. The muscles were small and showed no evidence of hypertrophy. The legs were not involved.

Lymphatic Angiomata.—Dr. Joseph Fraenkel presented a man who had symmetrical tumefactions in preauricular space, over the upper part of the sternum, between the upper borders of the shoulders, and also in the abdominal wall. The man gave a history of chronic alcoholism. The speaker said that according to the modern conception this disorder was a localized disease of the lymphatic glands and vessels—in other words, a lymphatic angioma. Since the admission of this patient to the Montefiore Hospital he had developed rather acute tuberculosis. According to the literature, thyroid medication in such cases caused a diminution of the body weight, although the tumors, despite their close resemblance to lipomata, remained unchanged.

Multiple Neurofibromata.—Dr. Fraenkel presented specimens from a patient who had long been in the Montefiore Hospital. The patient was a woman, who was thirty-one at the time of her death. Her family history was excellent, and she had been well up to eleven years ago. At that time she had given birth to a still-born child, and claimed that shortly afterward she had developed a tumor on the right side of the abdominal wall. Soon after this the left lower extremity became contracted. On admission to the hospital there were contractures of both lower and upper extremities, and the diagnosis was hysterical contractures. In the later stages she presented the picture of hysterical chorea. There were very irregularly distributed atrophies and changes in the reaction of the muscles of the upper extremity, and in some of the muscles of the lower extremities. There was also total paraplegia. There were no trophic disturbances. At the autopsy a number of tumors, neurofibromata, were found, One of these almost totally compressed the cord. The brachial plexus was the seat of numerous neurofibromata.

Dr. Joseph Collins said that cases of multiple neurofibromata must be extremely rare, as he had just seen his first case of the kind. This patient was a smoker, who came to the clinic stating that he had suddenly begun to experience pain in the right arm and shoulder, and that pain and inability were increasing. Twelve years ago he had had a somewhat similar condition, but had recovered from it, and the history indicated that there had been several other similar but slighter attacks. Examination showed that the musculospiral, the circumflex and the suprascapular nerves were the ones particularly affected. They were tender on both superficial and deep pressure. Investigation showed no less than seventy tumors in different parts of the body, varying in size from one-fourth to one-half an inch. Two of these tumors could be felt in the inferior border of the axillary space where the external division of the brachial plexus was situated. It was, therefore, fair to infer that these tumors were similar to those found in the other parts of the body, and by an implication of that trunk had given rise to the pressure neuritis from which the patient was suffering.

Dr. Harlow Brooks said that at the January meeting of the New York Pathological Society a specimen of neurofibroma had been shown. Only the motor nerves were involved and the tuberosities were almost untouched. There was apparently a complete [illegible] of the nerve fibers.

The Histrionic Element of Mental Disease.—Dr. Theodore H. Kellogg presented a paper on this subject, which, he said, was not only an interesting study, but of real diagnostic importance. Shakespeare had recognized that the [illegible] mental disease [illegible] place. The acting was involuntary at times and intentional in other insane persons. The maniacal patient was sometimes driven by vivid hallucinations to emotional acting. There was nothing more spectacular than a powerful man wrought up by hallucinations and delusions. The most persistent and intentional forms were seen in paranoia. The theatrical stage afforded nothing more alluring than the insane leading a crowd of sane persons from their sober avocations into all sorts of vagaries of religious belief. It was the rule that whatever had been attained by laborious effort was generally abandoned in mental disease, and hence the professional actor showed no special tendency to act in the insane. A number of cases of erotomania had come under his observation which had been characterized by most persistent acting. Jealousy was one of the most powerful passions, and when it had insane intensity it led to the most tragic performances. Mental patients were prone to mimic those around them most persistently and cleverly. In most large hospitals for the insane were to be found those acting as buffoons for the edification of themselves and others. Malingering rôles were sometimes acted for weeks and months, and sometimes the patient even burlesqued the mental disease. They sometimes concealed their real symptoms and denied the existence of delusions in order to secure discharge from asylums. It was well understood that prolonged acting might lead to insanity, but it was not so generally known that when the histrionic element was repressed it would tend to interfere with the cure of the mental disease. The recognition of the histrionic element as an integral part of mental disease shed light on some obscure phases of mental pathology, and had practical bearing on the prognosis and treatment of mental maladies.

Dr. Lyon said that the author of the paper had enjoyed unusual opportunities for observing insanity in all its forms, and the instances cited were undoubtedly the exceptions rather than the rule. There were not many who act a consistent rôle for any length of time. He had known some of those patients who were trying to act the rôle of a certain personage halt for a moment when confronted with the statement that this was not the true impersonation. He agreed with the reader of the paper that it was well to discourage, without actively combating, these delusions.

Dr. Diefendorf said that the paper was exceedingly interesting from a descriptive standpoint. He could not agree with the statement that the histrionic element was of great prognostic and diagnostic value. Such acting was said to be the expression of morbid impulses, and that they occurred in connection with grandiose ideas in paranoia, yet in the one class the prognosis was good, and in the other it was very unfavorable.

Dr. Ralph W. Parsons described a number of striking and amusing cases illustrating the histrionic element. He said that in these cases the imagination was the predominant element, and that there was often a reversion to the mental state found in children or in primitive races.

Dr. Noble, of Middletown, Conn., said that the patients he had met with who had displayed the histrionic element had rarely been consistent; they would not carry out the entire character impersonated, as an actor on the stage would do. Whether this was because of deficient knowledge of the character impersonated or because of a deficiency in histrionic ability he could not say. He had always looked upon this element as unfavorable, probably because it was so largely seen in paranoiacs.

Conditions for Psychiatric Research.—Dr. Adolf Meyer read this paper. He spoke of the founding of the New York Pathological Institute of New York State, and of the causes which had led to the failure of this work. He said that he had hesitated long before accepting the present honorable position and the task of reorganizing the institute and making it more generally useful. He had been told that the hospitals for the insane would not receive what they most needed if the institute began its work with research. The scientific spirit in the hospitals should be encouraged and fostered in every way possible, and hence clinical and pathological work should be done as far as possible in these hospitals under the supervision of the institute. The central institute should offer to the hospitals advanced instruction of clinical [illegible]. The central institute should not, however, [illegible] research. The safest starting point was undoubtedly actual experience. The pathologist of the hospital for the insane had found himself hedged in by various matters, and the hospital staff so engrossed with routine work as to have no time or inclination for original scientific investigation. The speaker then went on to point out many of the inaccuracies of symptomatology and the shortcomings of histology as applied to psychiatry. In his opinion, the staffs of the hospitals for the insane were entirely too small to do their work well. Psychiatry knew little as yet of diseases, as that term was used in connection with other parts of the body; in other words, it knew little of pathological entities. In no other field of medicine were absolutely accurate records so useful as in psychiatry, yet where were such records to be found? The effort of the present day should be to improve the records and do away with the prevalent impressionist method. Dr. Dent, of the Manhattan Hospital, had agreed to give the necessary clinical material for a start, and a chemical laboratory and a histological laboratory for study in clinical psychiatry would be established, and, in time, a psychological department would be added. All those in charge must be physicians especially interested in psychiatry. The assistant physicians in all the hospitals should be encouraged to do good work according to the recognized modern scientific methods. The new movement must be a natural outgrowth of the present conditions.

Dr. Lyon thought the workers in the hospitals for the insane would very generally welcome such help as had been offered in outline in this paper. He had long felt that clinical and laboratory work should be practically united.

Dr. Smith Ely Jelliffe congratulated the reader of the paper and pledged his hearty co-operation. He said that he knew the stress of work laid upon the hospital interne and sympathized with him, and for this reason he thought the suggestions contained in the paper were most judicious.

Pathological Conditions Impairing the Singing Voice.—F. X. Spranger, in discussing this subject, says that variations in the thickness of the mucosa in the nasal accessory sinuses play an important part in changes of the quality of tone. By acute inflammation or hyperæmia of the membrane, the voice can be impaired and *sometimes even improved*. Instances are numerous in which singers, suffering from a severe cold, will hesitate to sing, but when fairly started they feel they never sang so well in their whole career, and they probably will never again be as pleased with their voice unless similar conditions arise; the thickening of the mucous membrane may have caused the proper nasal and sinus capacities to intensify the vibrations of the voice to their utmost.—*Detroit Medical Journal*.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 22, 1902:

	Cases.	Deaths.
Measles	814	25
Diphtheria and croup	350	39
Scarlet fever	351	33
Smallpox	66	13
Varicella	141	..
Tuberculosis	265	170
Typhoid fever	21	6
Cerebro-spinal meningitis	..	4

The Latest Development of Finsen's Light Treatment of Lupus.—Recent experiments made in the Finsen Institute with various metals instead of carbon electrodes have led to a most surprising discovery, namely, that iron gives a spectrum which is enormously rich in chemical rays but almost devoid of heat rays. Utilizing this peculiarity of the spectrum of iron, a Finsen lamp has been constructed the electrodes of which are composed of hollow cylindrical pieces of iron, which are cooled by water circulating inside them. The light produced by the new lamp is very intense; within two minutes a bactericidal effect is produced as great as that produced by the old Finsen light within an hour. The experiments were arranged as follows: A continuous current of five ampères was employed for lighting the lamp, hollow iron electrodes with a central water-cooling arrangement being used. The electric pressure amounted to 40 volts; the distance between the object and the arc-light was 10 cm. (four inches). The light was *not* collected with a lens. The test microbes were: Bacillus tuberculosis, B. typhi abdominalis, B. choleræ asiaticæ, Streptococcus pyogenes aureus, Bacterium coli communis, and gonococcus. Gonococcus and tubercle bacilli were cultivated in 2 per cent. glycerin agar coated with sterilized blood, the other microbes in 15 per cent. nutrient gelatine. Figures are given showing the bactericidal power of the new lamp over the apparatus formerly in use.

An Important Correction.—In the March number of the *American Journal of Nursing* occurs an editorial paragraph under the above caption, referring to a difference of opinion reported to have occurred at the recent meeting of the New York State Nurses' Association. The paragraph reads as follows: "One of the many sensational newspaper reports we feel we may, without loss of dignity, correct. It relates to the discussion held on Article V of the president's by-laws, providing for 'three trustees,' which raised the question of the advisability of including physicians in the management of the association. Miss Dock drew attention to the troubles and difficulties which had arisen in other countries by giving the control of nurses' organizations into the hands of medical men, arguing that the most ethical men, whom we most esteem, would refuse to hold such positions, while they would always be willing to advise and help us, while those who would be willing to assume such positions would be the ones who could not always be trusted to work for our interests, and that they might prevent our development as individuals and as women. She finished by saying, 'As my only brother is a medical man, I think I cannot be accused of disloyalty to the medical profession.' Miss Palmer then arose and claimed the right to endorse all that Miss Dock had said, as she was the daughter of a physician. The newspaper reports of these remarks represented them as an attack upon physicians, which was wholly false."

Glandular Fever.—J. Park West reports two cases in full, and puts the question, Is glandular fever a distinct disease? If the answer is to be in the negative, it seems to him that it can only be that form of influenza accompanied by catarrhal inflammation of the upper respiratory tract, in which there is enlargement of the cervical lymphatics, and comparatively frequent suppuration in the retropharynx and ears. There are no grounds upon which to suppose it to be a modified type of any of the other known acute infections, nor an irregular form of any of the acute exanthematous diseases. The symptom-complex resembles catarrhal influenza in the sudden outset, high temperature, muscular soreness, prostration and slow convalescence. But in glandular fever there is not local inflammation of nodes, which, however, enlarge in a regular and peculiar manner. Influenza is an epidemic disease, affecting adults primarily—glandular fever is restricted to house epidemics and rarely affects adults. Influenza is generally ascribed to Pfeiffer's bacillus, which has never been found in glandular fever. On the whole, the author is convinced that it is a distinct, specific infection, and not merely an enlargement of certain groups of nodes due to some local or accidental infection, nor a form of any other disease.—*St. Louis Courier of Medicine.*

A Case of Myelitis, Exhibiting the Results of Co-ordination Exercises.—John K. Mitchell reports the case of a young man suffering from myelitis as a result of typhoid fever which he had two years previously. Lumbar puncture failed to secure fluid. Careful treatment with exercises was continued through the summer. At first he was kept entirely in bed, the legs exercised with co-ordinate and resisting movements while he lay upon his back. In three or four weeks he was allowed to get up, with crutches or sticks, and was instructed in standing exercises with his back against the wall, at first with the eyes open, then with the eyes closed, and presently moving away from the wall a little. As his legs grew stronger, all the exercises were elaborated. They were never allowed to go to the point of fatigue, and he was encouraged to do them for a short time several times a day, rather than to attempt to do too much at once. He had a relapse after leaving the hospital, from over exertion, but again improved under systematic treatment. His station is now perfect, whether eyes are open or closed. He can stand on one leg easily, walk steadily forward or backward, and shows excellent balance in various complicated movements.—*The Journal of Nervous and Mental Diseases.*

Complications of Fractures and Their Management.—Duncan Eve treats the subject practically. Injuries to soft parts as immediate complications often demand special treatment; lacerated muscles require suturing, or, if macerated, removal. Injuries of the viscera are to be dealt with; large bloodvessels are frequently lacerated. Traumatic aneurysms are sometimes associated with fractures; displaced bone against a vessel may impede the circulation and cause gangrene. Injury to nerves is not uncommon. Ulceration, sloughing and gangrene, due to tight bandages or pressure of splints, are dangers always to be guarded against. The tips of fingers and toes should be left exposed, in order to observe the circulation. Fat embolism is a condition peculiar to fractures, comes on about the fourth day, and is usually fatal. Muscular spasm often persists, and is best overcome by constant traction. Atrophy of the limb takes place in all fractures, chiefly as a result of disuse, but gradually disappears with use. Pain, or neuralgia, or paralysis may be due to the involvement of a nerve in callus, and can be relieved by freeing the nerve. The author takes up the complication of special bones, and gives directions for their treatment.—*The Southern Practitioner.*

Diet in Nephritis.—Kaufmann and Mohr have undertaken experimental investigations in order to ascertain whether or not it is advisable to exclude meat from the diet in chronic nephritis, and if not, what kinds of meat are permissible. They selected patients with chronic parenchymatous and chronic interstitial nephritis, and [illegible] them for a given time upon a carefully specified diet. Daily estimations of the nitrogen and albumin elimination were made during that period and the clinical appearances were also taken account of. As the result of their work they believe that the exclusive administration of various kinds of meat or milk is without appreciable effect upon the course of the disease. The time-honored opinion that dark meat is injurious to nephritis is without foundation. Observation shows that nitrogen and albumin elimination varies within certain limits totally independent of what the diet may be. In different cases the most favorable periods of such elimination may occur with the exclusive administration of "dark" meat, with that of white meat or that of milk. These statements apply only to chronic nephritis. The acute form of the disease has not been considered by the authors.—*Zeitschrift für klinische Medizin.*

Mixed Typhoid and Malarial Infection.—L. Rho says that the possible co-existence of these two diseases is an acknowledged fact. There is no fusion of the two infectious elements but simply a coexistence or a complication in which the two febrile cycles have a marked tendency to retain their individual independence. As a rule, the typhoid infection is superadded to the malaria, Laveran's hæmatozoon remaining quiescent during the entire period of the typhoid, to return to activity during convalescence. In quite exceptional cases malaria is added to the typhoid. Quinine usually overcomes the malaria. The gravity of the combination of diseases depends upon the power of resistance of the individual and the intensity and malignity of each of the infections. An exact understanding of the epidemiology of endemic fevers in tropical countries can only be attained by a systematic plan of research directed to examination of the blood for the hæmosporidium, diazo-reaction of the urine, serum reaction with the *micrococcus melitensis*, serum reaction with the Eberth bacillus, and the application of rapid processes for the differentiation of the typhoid and the coli bacillus (Elsner's method, etc.). —*Annali di Medicina Navale.*

Snake Venom in Relation to Hæmolysis, Bacteriolysis, and Toxicity.—Simon Flexner, from the results of his experimentation, concludes that venom contains principles which are agglutinating and discoloring for white blood corpuscles. The agglutinating principles may be identical for both white and red cells. The discoloring principle for leucocytes is distinct from that for red cells. In order that solution of venomized leucocytes shall occur a complement-containing fluid is required. The several varieties of white cells of the rabbit's blood show different susceptibilities to the action of venom. All venoms when used in suitable quantities destroy the bactericidal properties of many normal blood sera. The manner of this destruction consists in the fixation of the serum-complements by the venoms. Venoms have no action upon the intermediary bodies of serum. If the venom is incapable of uniting with the serum-complement, then the original bactericidal properties remain unaffected by the presence of the venom. Calmette's antivenene neutralizes venom, and removes both the hæmolytic and the anti-bacteriolytic actions.—*University of Pennsylvania Medical Bulletin.*

How to Make the Clove Hitch.—J. T. Woods gives the following directions: Take a roller bandage of proper width and length, dip it in water, wring mildly by squeezing, and apply a half dozen turns snugly around the part at the point where the extension hitch is to be applied. Taking a smooth, strong, pliable cord as long as desired for purposes of extension, and ascertaining its middle, place that point on the roller bandage, allowing the tails to hang on either side. Crossing them beneath and bringing each of the tails up on the opposite side immediately below the first round applied and tie a half knot. Thus far the cord should be applied very loosely. Now observing the tails of the half knot, one will be found at the distal side of the first encircling cord, and the other on the proximal side that is next to the first cord circle. If now, the first or upper cord be loosened sufficiently to pass this tail under it, and all is then drawn quite taut, the clove hitch is formed. The bandage must be quite damp and lapped snugly, and the cord drawn tight, before traction is commenced.—*[illegible] Medical and Surgical Reporter.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended March 22, 1902:

SMALLPOX—UNITED STATES.		CASES.	DEATHS.

PATHOLOGICAL, THERAPEUTIC, AND CLINICAL NOTES ON A FEW CASES OF MALARIAL INFECTION.

BY J. HERBERT FORD, B.S., A.M., M.D.,
FIRST LIEUTENANT, ASSISTANT SURGEON U. S. A., PROFESSOR OF DISEASES OF THE TROPICS, COLUMBIA MEDICAL COLLEGE, WASHINGTON, D. C.

SINCE the malarial parasites are no more protean in their morphology than in their clinical manifestations, the few cases here discussed can neither be regarded as unusual nor as anomalous. Among this class those to be first considered were characterized by an accentuation, in some particular organ or organs, of those morbid processes which occur therein in all cases of infection, but usually without sufficient intensity to cause conspicuous local symptoms. The cases here mentioned, illustrating this, are a few extreme ones, in which these local symptoms had been so pronounced that, prior to admission to hospital, they alone had received attention.

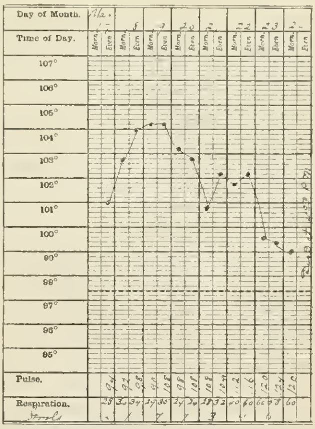
Local manifestations of malaria, unattended by general symptoms, usually take the form of trigeminal neuralgia, cephalalgia, or pseudorheumatic pains in various muscles. Cases of neuralgia are, in my experience, rare; only three having come under observation in a series of about eleven hundred cases of malaria. In two of these the first and second branches of the right trigeminus were affected; in the third, in addition to these, the supra-orbital branch of the left trigeminus. In all the pain was severe, paroxysmal, obstinate, of the usual neuralgia type, but unattended by atrophic changes in the seat of its occurrence. In no case was there observed any tendency to that regular periodicity in the recurrence of the paroxysms which the literature on the subject would lead one to expect. All the patients appeared to be otherwise in good health; slight enlargement of the spleen was demonstrable, and the æstivo-autumnal parasite, in all stages of its development and involution, was found in large numbers in the blood. The character of the parasite found may account for the irregularity of the paroxysms.

Cephalalgias of the same class as the neuralgias just mentioned are quite frequent, but offer nothing distinctive. Usually they are general in character, not at first severe, but progressive until other manifestations of malaria appear. When no facilities for blood examination are at hand these cases may at first be mistaken for old cases of heat exhaustion, in which very persistent or recurrent cephalalgia frequently occurs. But in the latter there are neurotic symptoms (sometimes very slight). If heat exhaustion is complicated by malarial infection, a diagnosis in the field is frequently impossible until enlargement of the spleen can be detected. This fact is somewhat important, since in this class the administration of quinine seems to do more harm than good, and reliance must be placed upon cinchonidia, eucalyptus, arsenic, and what is more potential, a change of climate.

The pseudorheumatic type, so-called for want of a better term, is characterized by pains in the larger muscles, especially those of the abdomen and the front of the thighs. As a rule, the pain is dull and persistent, at first aggravated by motion, then relieved thereby, but later, after a rest, quite as intense as at first. It is not usually severe, and occurs most frequently in those cases in which malaria has complicated chronic intestinal disease. In all probability impaired metabolism is a more immediate cause than are the toxic products attending the development of the hæmacytozoa.

When the pain is confined to the abdominal muscles it may simulate that of appendicitis, though it is usually more diffuse. The following cases bearing upon this case may be cited:

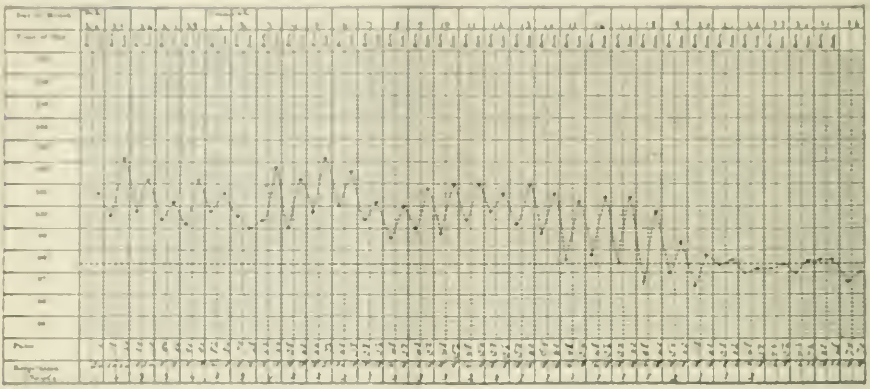
CASE I.—Private "R," twenty-three years old, well built, muscular, no history of appendicitis, typhoid fever, dysentery, or recent diarrhœa. Had a mild attack of "malarial fever" one month prior to admission. Health otherwise had been excellent. States that on March 23, 1900, he was seized with pain in the right iliac fossa, which gradually increased in severity until after two hours he was compelled to go to his quarters. His condition underwent slight temporary improvement, but on the 26th it suddenly became worse, and the patient was at once transferred to the hospital with a diagnosis of "acute catarrhal appendicitis." At this time his temperature was 97°; there was no nausea, vomiting, constipation, or any of the classical symptoms of appendicitis, except the pain and slight flexure of the right thigh. Slight enlargement of the spleen could be detected. Medical treatment proved unavailing, and as the patient's suffering was rapidly becoming greater and the temperature was rising, I operated for appendicitis. The appendix, five and one-quarter inches long, with a mesentery extending to within half an inch of the tip, was found lying



CASE I.—W. C., civilian, æt. twenty. Pneumonia, Pleurisy, Malarial and Æstivo-autumnal Fever. Second Reserve Hospital, Manila.

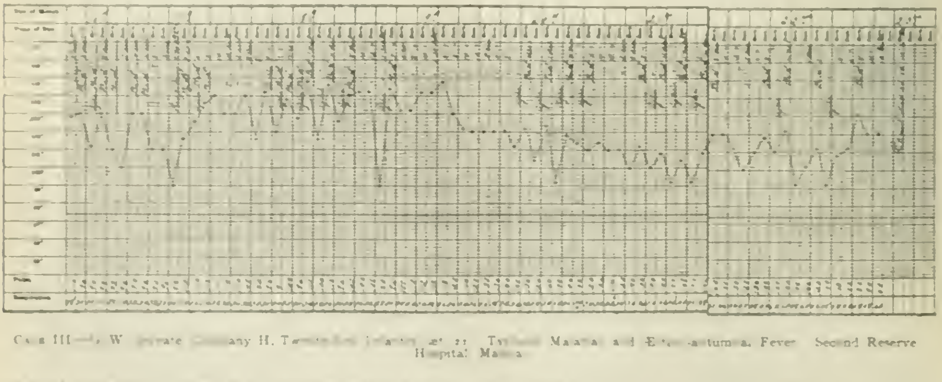
quite free, with no evidence whatever of old or recent inflammation or any other pathological condition either in the organ itself or in its vicinity. Examination of the appendix after removal gave no evidence of a catarrhal condition either on general or histological examination. Two small fecal masses about the size of grape-seed were found in its lumen but readily dissolved in a few drops of normal salt solution. No inflammation of the mucosa could be found at the points where these masses had rested, nor at any other points in the culdesac. Next day the patient felt easier, but on the second day he complained that at the site of the wound the pain was of the same heavy boring character, and quite as severe as that before the operation. The temperature had now risen to 101°; the examination of the blood made at this time revealed the æstivo-autumnal parasite present in the hyaline stage in large numbers, a few ovoids, crescents, and various intermediary forms. The use of quinine and arsenic caused a gradual amelioration of the symptoms, but it was not until the fourth day, when the patient was thoroughly cinchonized, that the pain disappeared. The wound healed by first intention, and recovery was uneventful. Five weeks later the patient was readmitted with all his original symptoms, even to the subnormal temperature. Quinine was again administered, but no local treatment was employed. In three days the patient claimed that he was well, and rejoined his company.

In this case it might be suggested that the fecal masses found might have caused appendicular colic—a condition which I have never seen described, but which it is quite conceivable may exist. But as there was no evidence of inflammation of the mucosa, and the pain was not of a colicky nature, and as masses of much greater size and hardness, whose presence has given rise to no symptoms, are frequently found in the appendix after death, I am not inclined to ascribe the pain occurring in this patient to disease of the appendix. A diagnosis of hysteria can, I think, be excluded because of the general considerations and the trend of the case.



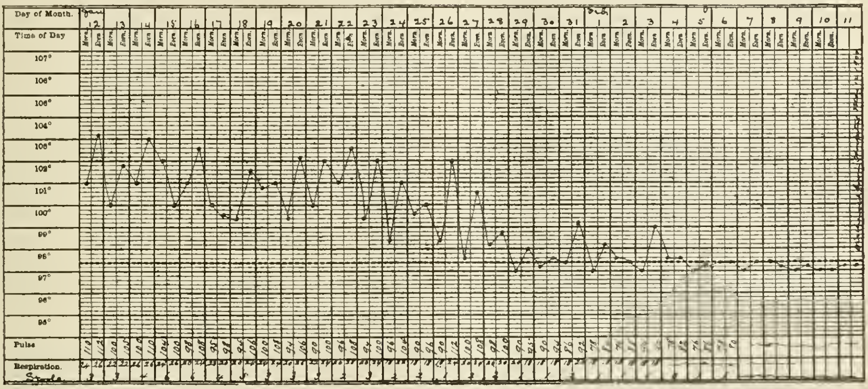
Case II.—P. H., private, Company C, Forty-second Infantry. Malarial Fever (tertian) and Typhoid Fever. Second Reserve Hospital, Manila.

Reference may be made here to the post-operative rise of temperature which all surgeons in Manila encounter; usually it is less than two and one-half degrees, and becomes evident within twenty-four hours, lasts from two to eight days, and is correlative with neither the severity nor the length of the operation. Popularly it is ascribed to latent malarial infection, and during the nine months that I did the surgical work at the Second Reserve Hospital I certainly saw it much more frequently during the first part of that service, when malaria was most prevalent, than I did when this disease was on the wane. But there is a large number of cases in which there is no history of malaria, in which the blood examinations are negative, and in which this fever disappears spontaneously. While it is probable that in some cases malaria may be a cause or a causative factor in its production, I believe that, in general, it is merely due to a disturbance of the nervous centers, whose unstability in the tropics is well known.



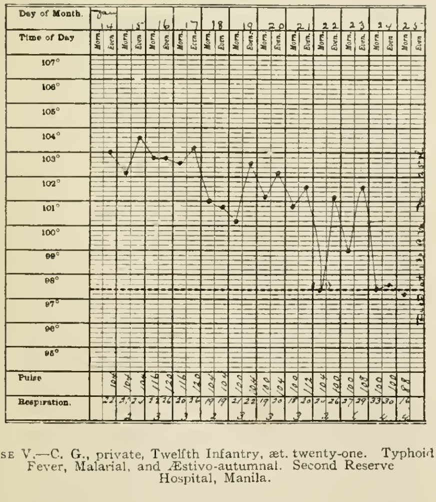
Case III.—J. W., private, Company H, Twenty-first Infantry, æt. 22. Typhoid, Malarial and Æstivo-autumnal Fever. Second Reserve Hospital, Manila.

Case II.—This patient, when first seen, was suffering from malarial cachexia, which had developed in Cuba about three months before. The only symptoms of appendicitis in this case were the pain in the right iliac fossa and irregular pyrexia oscillating between 99°F. and 102°F. Neither the general condition, treated by quinine and arsenic in moderate doses, nor the local one, treated by rest, salines and ice bag, improved patient in the slightest degree. Operative interference was suggested, but it was decided that heavier dosage of quinine and arsenic should first be employed. To this end one and one-fourth grams of the former and fifteen drops of Fowler's solution of the latter were given three times daily. Both the local and the general condition improved at once.



Case IV.—R. L., civilian, æt. thirty. Mixed Infection, Typhoid, Malarial, and Æstivo-autumnal. Second Reserve Hospital, Manila.

Cases III., IV., and V. were in all respects similar to case I., but in these no treatment of the local condition was employed, and with a view to confirming my suspicions,* bromides were given for two days and other medication withheld. Cases III. and IV. remained in *statu quo*, and case V. became slightly worse. The administration of antiperiodics in large doses dissipated all local symptoms in cases III. and IV. in three days; in case V. in four days.



Case V.—C. G., private, Twelfth Infantry, æt. twenty-one. Typhoid Fever, Malarial, and Æstivo-autumnal. Second Reserve Hospital, Manila.

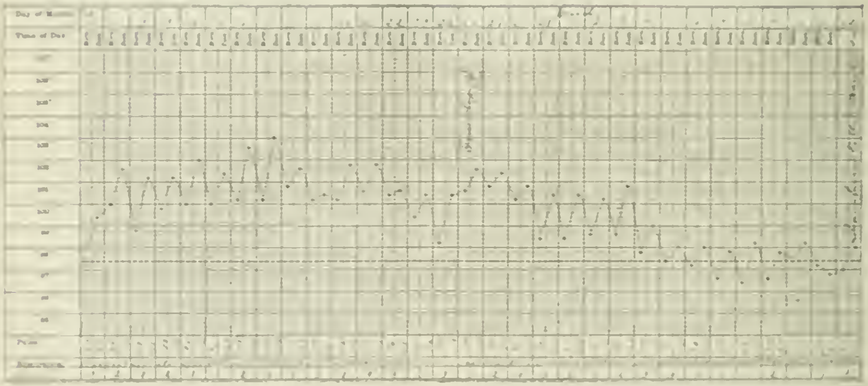
In these five cases there was either a history of malarial fever about one month prior to admission, or a well-marked malarial cachexia; in all, the spleen was enlarged; in all, the æstivo-autumnal parasite was found in the blood in all stages of its development and involution; in all, the condition was progressive, and in none did it ameliorate until antiperiodics were employed. I have carefully excluded several other cases, similar to those mentioned, but in which a possible history of appendicitis could not be obtained. It may be suggested that all these cases are merely illustrations of two separate coexistent conditions, the one general, the other local, but the negative discoveries in case I., and the clinical course in cases III., IV., and V., which I ventured to use as control observations, have not led me to that conclusion. Although the classical symptoms in appendicitis are often much distorted or entirely prevented, yet, I believe, they have never proven curable by antiperiodics. The cases are of interest in illustrating the localized pains which often occur in malarial conditions, and they offer a fairly distinct symptomatology, and there are few difficulties in diagnosis. In this connection it is interesting to note recent publications on malaria causing symptoms simulating those of salpingitis.

Cases of bronchial and pulmonic inflammation, in which malaria played at first an unrecognized part, have occurred in my experience in only three especially severe cases. The first of these, case VI., seen in the General Hospital at Fort McPherson, was a patient recently returned from Cuba, with persistent bronchitis and, later, capillary pneumonia. He was very asthenic with beginning cachexia. Pyrexia was irregular, ranging from 99° to 103°. The blood was not examined until the patient had been in hospital eleven days; it then showed great numbers of the æstivo-autumnal parasites in all stages of development. The patient's condition, both general and local, had meanwhile become worse, as the catarrhal process had extended to the smaller tubes. Quinine, in doses of 1 gm. t.i.d., and other medication, aimed at the local condition, having proved quite useless, I adopted a suggestion of Major Blair D. Taylor, Surgeon U. S. A., and gave quinine in doses in 1¼ gms. t.i.d., and Fowler's solution, beginning with five drops t.i.d. and increasing as rapidly as possible until twenty-five drops t.i.d. were being taken. No other medication was employed. The patient began to improve promptly, but convalescence was protracted.

Case VII.—This patient, like the preceding one, had recently come from Cuba. No history was obtainable, except that he had been ill for about two weeks prior to admission. The patient was well nourished. The pulmonary symptoms were those of diffuse severe catarrhal pneumonia, with hypostatic consolidation at the bases. The respirations on admission averaged thirty-two per minute, but gradually increased, till thirty-seven per minute were counted. Expectoration was scanty, frothy, not particularly viscous, and sometimes blood-stained. Examination for the diplococcus lanceolatus was negative. The pulse was full, fairly strong, ranging from 118 at first to 136. The spleen was enlarged. The temperature was extremely irregular, sometimes normal, but more frequently ranging from 100° to 101.5° F., seldom reaching 102°, and never rising above 102.5°. The mental condition was variable; usually there was not only mental dulness and headache, but at one time, just prior to the blood examination, there was muttering delirium with retraction of the head, the delirium and retraction being, indeed, at one time so marked that cerebrospinal meningitis was suggested. Cephalalgia was very noticeable. The patient had reached me with a diagnosis of "influenza," and for some time, as this is quite a protean disease, I followed a palliative line

right lung. The examination of the blood on March 17 showed the æstivo-autumnal parasite in various stages of its development and involution; on March 23 the same forms, somewhat less numerous, were seen with crescents and pigmented leucocytes. After death the parasites were found in the fluid expressed from the solidified lung, but it could not be determined that they existed here in greater frequency than in the general circulation. There had been no expectoration by means of which an attempt at diagnosis could be made, but the examination of bronchial mucus after death, for the diplococcus lanceolatus, was negative. There was no evidence of enteric disease before death, and the intestine appeared normal post-mortem. The spleen was deeply pigmented, somewhat enlarged, and [illegible].

Croupous pneumonia can be caused by too many agents, and generalizations from a single case are obviously too dangerous to permit me to state that the pulmonary condition here was caused by malaria alone. Statements to that effect have often been made, but generally, I believe, without adequate ground, and this case can do no more than suggest a possibility as the real causative agent may have been overlooked.



CASE VI.—H. C., private, Fourth Cavalry. [illegible] Typhoid and Malarial Fever and Æ[illegible]

of treatment, and gave quinine in average doses. At length I examined the blood and found it swarming with æstivo-autumnal parasites. Frequently three crescents were found in the field. The Widal test was negative. The same line of treatment was followed as in the preceding case with the result that the downward course of the disease was promptly checked and recovery eventually ensued.

Cases VI and VII gave me my first experience with tropical malaria, and from them I learned the inefficiency of quinine and arsenic when given in doses which I had heretofore considered maximum. It is probable that the season during which these patients were admitted (January) and the fact that they had just come from a much warmer climate, had much to do with the character of the disease.

Case VIII is the only one which I have seen in which pulmonary consolidation occurred in the course of malarial infection, though a similar case is mentioned in the syllabus of the committee sent by the Johns Hopkins University to study malaria in the Philippines. Both of these patients were negroes. In my case there was a history of recent malarial fever, but the primary cause of admission was the pulmonary condition. This offered nothing distinctive (see Chart I); indeed, the clinical picture was merely that of croupous pneumonia involving the entire

There is a growing tendency among physicians in the Philippines to ascribe to malarial infection an etiological influence in many of the cases of chronic diarrhœa and dysentery. As a rule, these cases present nothing distinctive, but sometimes the wasting is more rapid than might be expected, and the cachexia which develops is attended with pigmentation of the skin. The spleen is also enlarged, but to a very variable degree, the enlargement being apparently more correlative with duration than with the intensity of the disease. The temperature is generally normal, or at least under 99.5° F., even when numerous parasites are found in the blood. The severity of the infection that may exist without much, if any, fever is, indeed, the most noteworthy feature of the disease. So persistent and yet so obscure is the malaria, that Manson has suggested that in all cases of chronic diarrhœa which do not respond to treatment an examination of the blood be made. Recovery is generally impossible unless the malarial element be removed. The converse, unfortunately, does not hold, for many patients from whose peripheral circulation the parasite has long since disappeared, though they may improve, do not recover without protracted treatment and a change of climate. It is possible that the absence of general manifestations of malaria may be due to the lodgement of the parasites in large numbers in intestinal capillaries, and to partial elimination of the toxines by osmosis, while the chronicity of the diarrhœa is due to the irritation dependent thereupon.

There is a type of malaria quite prevalent in Cuba, but, in my experience at least, quite rare in the Philippines, in which the clinical picture may strongly simulate yellow fever. But two cases of this kind have come to my notice, and as these developed in the field in the Philippines, no satisfactory notes or temperature records could be taken. The fact is mentioned, however, since both patients gave a history of this type of malaria experienced about one year previously in Cuba, and an illustration is thus offered of how the disease may not only persist for some time after the subsidence of all symptoms, but that when it recurs it may resume its former quite specialized manifestations.

Closely associated with this is acute malarial nephritis, which has occurred in about 1½ per cent. of the cases of malaria admitted to the Second Reserve Hospital, in Manila. With very few exceptions it has not been severe, and has generally responded to treatment. The condition is one of obvious interest, but has recently received such voluminous consideration that its discussion here is unnecessary. In passing, however, I must allude to the statement recently made by Dr. Smith, A.A., Surgeon U. S. A., to the effect that quinine is not only a useless, but even a dangerous, drug when given in this disease, and that calomel is the best remedy available—indeed, almost a specific. I have seen only one case of malarial nephritis contracted in Cuba, and it is quite possible that although this case was severe, my success in treating it with quinine was exceptional. But my success in treating with quinine the malarial nephritis found in Georgia and the Philippines, no matter of how great severity, is not only unexceptional, but is the common experience of many of the medical officers with whom I have discussed the subject. The patient with Cuban malaria I saw at the U. S. A. General Hospital at Fort McPherson, Georgia, whither he had been brought with a history of ever-increasing severity of his symptoms. When admitted he was cachetic, at times delirious, and in his lucid intervals complained of severe pains in the back and loins. The spleen was enlarged and the blood swarmed with æstivo-autumnal parasites. The urine contained blood, albumin, and hæmoglobin, and gave the other usual evidences of acute nephritis. The diazo reaction was not obtained. As the patient could not retain quinine taken by the mouth, it was given him hypodermically, in doses of 1¼ gms. three times a day, while the symptoms were treated as they arose. The patient responded well to treatment, and the improvement of the local condition was satisfactory, but it was two months before the cachexia had disappeared. In the Philippines, when it is possible that the type of malaria differs from that seen in Cuba—though some cases are, undoubtedly, recidives of Cuban malaria—I have used quinine in the treatment of malarial nephritis in doses which may appear dangerous, but which were necessary, and from which apparently no bad results ensued. Thus in two cases where the condition was especially severe, after I had used moderate doses of quinine for forty-eight hours without any apparent effect, I gave it in doses of 4½ gms. hypodermically, daily, for eleven days, in one case, and for two weeks in another. Recovery ensued. In justification of such enormous doses I can only state that before they were used the course of the disease was progressively and rapidly downward, and that they proved sufficient to check its progress. Both cases came in, without any former illness, from Calamba, a point on Laguna de Bay, where malaria was then exceptionally prevalent and severe. Now, however, malarial infections appear less severe than they were during the first year of the American occupation. They are certainly much milder in the Philippines than they are in Cuba. Half a gram of quinine, in solution, given per rectum daily, in divided doses, is now fully adequate to control Philippine malaria in the majority of cases.

While emphasizing the value of quinine in the treatment of malarial nephritis, I do not wish to deny that calomel is a valuable adjuvant. Its physiological action implies this fact, but unless it has an empirical value, such as that of ipecac in dysentery (a value which my experience has not led me to suspect), there is no apparent reason for assuming it that specific influence which Dr. Smith has described.

A mixed infection of the hæmocytozoa malariæ and the bacillus typhosus is now generally recognized to be possible, though extremely rare. In the course of upwards of two years' service in the Garfield Hospital in Washington, D. C., I never saw such a case, and the few cases which I here describe are all that have fallen under my observation after twenty months' experience with tropical and subtropical malaria.

Case VIII. (See Chart 2.)—Patient never had typhoid or malarial fever. For about ten days prior to admission had been listless, suffering from vague pains in the back and limbs, with occasional slight headache, and four days ago had had slight epistaxia. There was no history of a chill. The clinical picture at this time was that of a mild, uncomplicated case of typhoid fever. The expectant treatment of typhoid was followed, and the case ran an uneventful course as one of typhoid fever, except that toward the end the oscillation in temperature became rather greater than usually occurs. The pathological report was as follows:

February 24.—Widal negative. No malarial parasites.

March 10.—Widal positive. No malarial parasites.

March 15.—Widal positive. Tertian malarial parasites few.

March 18.—Widal positive. No malarial parasites. Pigmented leucocytes.

Case IX (See Chart 3).—This patient gave a history of chill, epistaxis and onset of fever about two weeks prior to admission. When first seen he was in an extremely weak and emaciated condition, temperature 103.8°. The clinical picture was like that seen in second week of typhoid fever, of very severe type, and probably aggravated by exercise. The mental condition was clouded, and no very definite history could be obtained. Hypostatic consolidation was already present in both lungs, and the prognosis offered was unfavorable.

A clinical diagnosis of typhoid fever was made. The course of the disease was not satisfactory, for the stupor deepened, carphologia developed, and the weakness progressively increased. Death occurred February 22. The pathological report of the blood examination is as follows:

February 16.—Widal positive. Hyaline actively amœboid æstivo-autumnal parasites. Macrocytes. Pigmented leucocytes.

The autopsy revealed the following facts:

Body.—That of a young man. Emaciated. Skin clear. Pupils slightly dilated, the right larger than the left. Mucous membranes and nails cyanosed. Teeth normal. Rigor mortis marked. Post-mortem

Discoloration of neck and back. Abdomen slightly distended.

Left pleural cavity.—Free from adhesions.

Left lung.—Most of lower lobe hypostatic. No evidence of tuberculosis.

Right pleural cavity.—Few old adhesions on external wall.

Right lung.—Hypostatic pneumonia of lower and most of middle lobe. It is beginning to invade the upper lobe. No evidence of tuberculosis.

Heart appears normal.

Left Kidney.—Five and one-half inches long. Capsule slightly adherent. Cortex eight mm. thick. Organ congested. Pyramids deeply congested.

Right kidney.—Five and one-half inches long. Capsule slightly adherent. Cortex four mm. thick in one place. Pyramids deeply congested.

Spleen.—Eight inches long by five and one-half inches wide. Rolls out at point of section. Very dark red.

Intestines.—Colon for ten inches below cæcum, somewhat reddened. Immediately above valve, Peyer's patches are swollen, but no ulceration exists at that point. Small patches are ulcerated eight inches above valve. Floor formed by muscular coat. Higher up, for a distance of four feet above the valve larger patches are inflamed but not ulcerated.

Anatomical Diagnosis.—Chief and determined cause of death: Typhoid fever. Colitis acute, mild. Acute splenic tumor. Nephritis subacute. Æstivo-autumnal malaria.

Microscopical and Chemical Findings.—Ante-mortem blood—February 15. Widal positive. Hyaline æstivo-autumnal malarial parasites. Macrocytes.

Post-mortem blood—February 25. Widal positive. The post-mortem examination of the blood gave the Widal reaction. No examination was then made for the malarial parasite.

Case IX. (See chart 4.)—Previous history negative. Present illness, of about ten days' duration prior to admission, was of insidious onset, not marked at any time by chill or epistaxis. On admission the patient was in fair general condition. The clinical picture was typical of that seen in the second week of typhoid fever, except that there was great congestion of the right lung with persistent cough and the occasional expectoration of blood-stained sputum. The course of the illness was uneventful. The pathological report:

January 28.—Amœboid and circular hyaline æstivo-autumnal parasites. Widal reaction positive. Immediate slowing and complete clumping in thirty minutes.

February 3.—Widal positive; numerous circular hyaline form. Pigmented leucocytes.

Case X.—This patient was admitted in a state of semi-coma and no notes of his previous history could be obtained. When I first saw him he was much emaciated but fairly strong, and there was nothing to suggest an early fatal event. The only unfavorable symptoms were the delirium and persistent tympanic disturbance of the abdomen. Progress was fairly satisfactory. Toward the end the pulse became weak and hypostatic congestion in both lungs at once became evident. Perforation occurred at 1.40 P.M. on the 24th, and on the following day the patient died in collapse. The pathologist reported as follows:

January 14.—Hyaline actively amœboid, crescent and ovoid forms of the malarial parasite. Macrocytes. Poikilocytosis. Widal reaction positive prompt.

January 24.—Few crescents and ovoids, few hyaline forms. No pigmented forms. Macrocytes. Leucocytes contain much pigment. Proportion of red corpuscles to plasma much reduced. Widal reaction prompt.

The post-mortem examination revealed the following condition:

Body.—Emaciated, skin brown, mucous membrane pale, finger nails cyanosed, [illegible] about axilla over abdomen and thighs. Chest well developed. Abdomen somewhat distended.

Abdominal cavity.—Peritoneal cavity filled with gas and purulent yellow fluid, one quart in amount. Intestinal peritoneum shows petechial hemorrhages. One hemorrhage area is of five mm. in diameter. Gall bladder moderately distended. Bladder contains a small amount of urine. Mesenteric glands very much enlarged. Appendix, six cm. long, has mesentery which contains a considerable amount of fat.

Spleen.—Seven inches by five inches. Capsule smooth, light in color. The tissue does not roll out at point of section. It is blackish brown in color and soft.

Right kidney.—Five inches by two and one-half inches. Capsule smooth, light in color, slightly adherent. Tissue rolls out at point of section. Cortex six to eight mm. thick. Pyramidal markings distinct. Margins of pyramids slightly congested.

Left kidney.—About same size, considerably congested. Cortex darkly congested. Malpighian bodies markedly congested.

Liver.—About sixteen inches long. Surface yellowish, light mottled color. Capsule smooth. Upon section the organ is light, pasty, distinctly fatty.

Intestines.—Contain numerous dark areas, one to two and one-half cm. in diameter, some black and gangrenous. One shows peritoneal coat only. Fecal matter oozes from a perforation five mm. in diameter eight inches above ileo-cæcal valve. Ulcer in whose floor the perforation is found is two cm. in diameter. Sigmoid flexure and ascending colon show numerous old ulcerations, most of which are nearly healed. From the vicinity of some can be squeezed gelatinous, thick, creamy, yellow pus, which appears to dissect up the mucous membrane. Some ulcers show centers five mm. in diameter not yet healed. Upper side of ileo-cæcal valve ulcerated and most of the mucous membrane denuded for a distance of four inches from that point up to the small intestine. Above this point for six inches are numerous small ulcers in a stage of healing. About eleven inches above the valve is an ulcer two and one-half cm. in diameter, with abrupt edges, with base formed by muscular and peritoneal coats. Near its border is a perforation one-half cm. in diameter. For four feet above the valve an ulcer is found every four inches; for the next three feet every three inches, the upper ones in a state of healing.

Right lung.—Collapsed. Bound to parietal wall by old firm adhesions, outer side, posteriorly, and about apex congested and crepitant.

Left lung.—Collapsed. Lower lobe congested and crepitant. No evidence of tuberculosis.

Pericardium.—Is distended with 100 c.c. of clear straw fluid.

Heart.—Size corresponds to size of individual. Right heart contains a small red clot. Valves normal. No evidence of sclerosis in aorta above bifurcation.

Brain.—Cortical vessels congested. Durameter over vertex and parietal areas bulging with clear fluid.

Case XI. (See Chart 6.)—This patient's previous history was negative. Had had a chill and slight epistaxis the second day prior to admission, and when he first came under my care presented the usual symptoms of typhoid fever when seen at its earliest stage. The course was quite uneventful, except that a hemorrhage occurred February 25, and that lysis seemed to be protracted. The pathologist reported as follows:

February 11.—Few hyaline and pigmented æstivo-autumnal parasites. Widal negative.

February 21.—Few hyaline parasites, æstivo-autumnal. Widal reaction, partial, considerable activity of the free bacilli continuing after three hours.

February 23.—Macrocytes. A few hyaline æstivo-autumnal parasites. Widal positive. Large clumping, considerable activity of free bacilli.

All of these cases were treated on the expectant plan, until it was found by the blood examination that they were of a dual character, and then quinine was used in doses of ½ gm. daily. It will be noted that this was not sufficient to destroy the parasite or drive it from the peripheral circulation, and it was invariably found necessary to increase this dosage before lysis was complete. In no cases were there any clinical evidences of the malarial infection. The lysis was irregular in the case of tertian infection, and in one case of æstivo-autumnal infection (Chart 5), but in all others here cited the temperature course offered nothing that might lead to a suspicion of a mixed infection. This protracted lysis is, I believe, generally observed in cases of typhoid fever complicated by tertian malaria. At Fort McPherson, in January, 1899, I saw two cases—one in the service of Dr. Watkins, A.A.S., U. S. A., and the other in the service of Dr. Rind, A.A.S., U. S. A., both of which ran a typical course until the fever began to decline. Then wide variations in temperature occurred, and an examination of the blood revealed a previously unsuspected tertian infection. I was told that several cases had been noticed in that hospital during the preceding autumn.

In this connection it is, perhaps, supererogatory for me to call attention to the frequent mistakes in diagnosis that occur from a lack of our recognition of the unclassified fevers of the tropics, but the subject is an important one, and I shall refer to it in closing. On various occasions I have seen patients with high fever (103 to 104.5°), who had not recently taken quinine, in whose blood no hæmocytozoa could be found, and who recovered without the use of antiperiodics, classed indiscriminately as malarial-fever patients. Thus in one series of about 7,000 patients, suffering with various ailments, malarial fever was stated to exist as the cause of admission or as a complication thereof in from 54 to 55 per cent. of all cases, the maximum being in January and February of each year, the minimum in July and August. Upon the arrival of a competent pathologist the average fell to about 10 per cent. and remained in that vicinity until the pathologist departed, when it immediately rose again. The diagnosis reached during the time of the pathologist's stay had been by means of the microscope only, due allowance being made for the recent use of antiperiodics, spontaneous convalescence, etc. The diagnosis reached at other times was clinical.

Similar errors occur in cases of other diseases, but attention should be directed to this field particularly, for here lie the greatest mass of errors and the greatest opportunity for investigation. Several types of unclassified fevers have prevailed in the Philippines since the American occupation, but lack of systematic study, and the observation of but few cases at any one time, have deterred many from pushing their investigations who would otherwise be interested. With the decline of hostilities, however, the exigencies of the service require less frequent changes of station on the part of medical officers, and thus greater opportunity will be given for the study required.

THE INFLUENCE OF SUPRARENALS IN PNEUMONIA.

By ETHAN ALLEN GRAY, M.D.,
CHICAGO ILL.

THE rather large mass of reports and other writings on the subject of suprarenals have given us a great deal of fact regarding the therapeutic action of the dried gland and of its active principles. Concerning the physiological action of the remedy, on the circulatory apparatus particularly, the scientists are not one.
